Preface

To be completed by Vitor.

The goal of this book is to provide a comprehensive and transparent description of the methodologies adopted and implemented in the Risk Modeller's Toolkit (RMTK).

It is freely distributed under an Affero GPL license (more information available at this link <http://www.gnu.org/licenses/agpl-3.0.html>)

1. Introduction

Recent years have seen the development of several free and open-source softwares for seismic risk assessment. The OpenQuake-engine developed by the Global Earthquake Model (GEM) Foundation is one such software which provides state-of-the-art scenario-based and probabilistic seismic hazard and risk calculators. The availability of such software has made it much easier for hazard and risk modellers to run complex analyses without needing to write their own implementations of the algorithms involved. However, the preparation of the input models for seismic risk analyses is often an equally challenging task, and the availability of tools to help modellers in this stage are very limited.

The main inputs required for a seismic risk analysis are a seismic hazard model, an exposure model, and a physical fragility or vulnerability model. A hazard model itself comprises three components: the seismogenic source model(s), the ground motion prediction equations and the logic tree to characterise the model-to-model uncertainty in an equation. The exposure model describes the locations and other characteristics of buildings within the region of interest. Finally, the physical fragility and vulnerability models describe the probability of damage and loss for different levels of ground shaking for the different building classes in the region of interest.

The lack of tools for model preparation may drive modellers to use tools that are not specifically designed for the creation of seismic hazard or risk models. Alternatively, modellers justifiably create their own implementations of standard methodologies, leading to a possible lack of consistency between different implementations even if the methods selected in the model preparation process were the same. Quality assurance and maintenance of code is another issue that modellers are required to deal with. There is clearly a strong motivation for extending the philosophy of open-source software development to the process of model preparation.

Thus, in addition to the OpenQuake software, GEM is now in the process of developing a set of tools to aid hazard and risk modellers during the model preparation stage. These tools are currently made available in the form of three "Modeller's Toolkit's":

- 1. The Hazard Modeller's Toolkit:** a suite of open-source tools for the preparation of seismogenic source models for application in probabilistic seismic hazard assessment (Weatherill, 2014)
- 2. The Ground Motion Toolkit:** a suite of open-source tools for analysis and interpretation of observed ground motions and ground motion prediction equations, for the purposes of GMPE selection in PSHA

3. The Risk Modeller’s Toolkit: a suite of open-source tools for the preparation of physical fragility and vulnerability models for application in seismic risk assessment, and for the post-processing and visualising of results from OpenQuake risk analyses

This user manual describes the set of tools and other functionality provided by the Risk Modeller’s Toolkit (RMTK). The RMTK makes it possible for a risk modeller to select from several commonly used methods to derive seismic fragility or vulnerability functions for individual buildings or a class of buildings. The currently available functionalities of the toolkit are shown graphically in Figure 1.1 and described in more detail in Section 1.2.

As with the OpenQuake-engine, the RMTK is developed primarily using the Python programming language and released under the GNU Affero open-source license. The RMTK software and user manual are updated regularly by scientists and engineers working within the Global Earthquake Model Foundation. The latest version of the software is available on an open GitHub repository: <https://github.com/GEMScienceTools/rmtk>. The user manual for the rmtk can be downloaded here: https://github.com/GEMScienceTools/rmtk_docs.

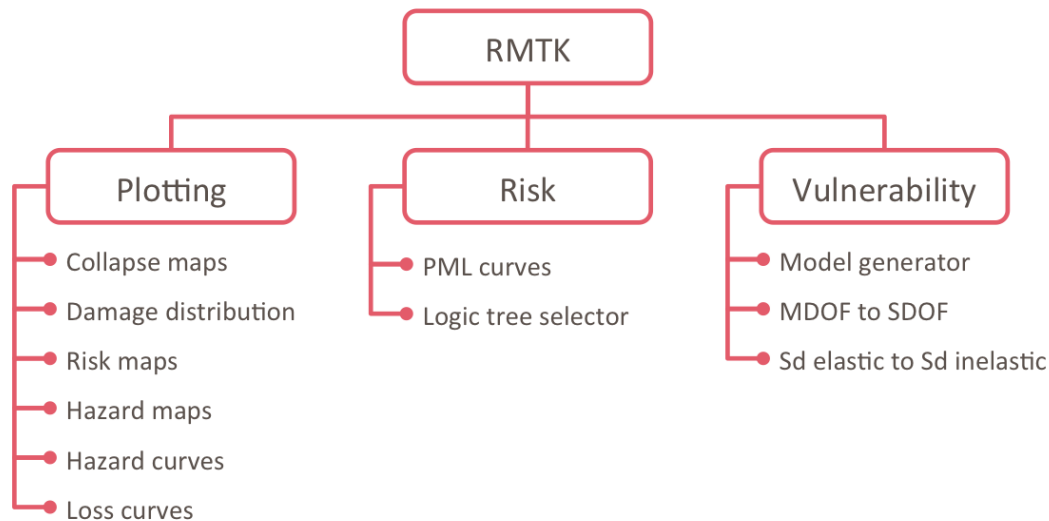

Figure 1.1 – The modular structure of the Risk Modeller’s Toolkit (RMTK), showing the currently available functionalities

1.1 Getting started

The Risk Modeller’s Toolkit makes extensive use of the Python programming language and the web-browser based interactive IPython notebook interface. As with OpenQuake, the preferred working environment is Ubuntu (12.04 or later) or Mac OS X. At present, the user must install the dependencies manually. An effort has been made to keep the number of additional dependencies to a minimum. More information regarding the current dependencies of the toolkit can be found at <http://github.com/GEMScienceTools/rmtk>.

The current dependencies are:

- Numpy and Scipy (included in the standard OpenQuake installation)
- Matplotlib (<http://matplotlib.org/>)

The Matplotlib library can be installed easily from the command line by:

```
~$ sudo pip install matplotlib
```

The Risk Modeller's Toolkit itself requires no specific installation. In a Unix/Linux environment you can simply download the code as a zipped package from the website shown previously, then unzip and move into the code directory. Alternatively you can download the code directly into any current repository with the command

```
~$ git clone https://github.com/GEMScienceTools/rmtk.git
```

To enable usage of the rmtk within any location in the operating system, OS X and Linux users should add the path to the rmtk folder to their profile file. This can be done as follows:

1. Using a command line text editor (e.g. VIM or Emacs), open the ~/.profile folder as follows:

```
~$ vim ~/.profile
```

2. At the bottom of the profile file add the line:

```
export PYTHONPATH=/path/to/rmtk/folder/:$PYTHONPATH
```

Where /path/to/rmtk/folder/ is the system path to the location of the rmtk folder (use the command pwd from within the rmtk folder to view the full system path).

3. Reload the profile file using the command

```
~$ source ~/.profile
```

The IPython Notebook is a browser-based notebook which provides support for interactive coding, text, mathematical expressions, inline plots and other rich media. Static notebooks can also be created for recording and distributing the results of the rich computations.

If you already have Python installed, you can get IPython along with the dependencies for the IPython notebook using pip:

```
~$ sudo pip install "ipython[notebook]"
```

A notebook session can be started via the command line:

```
~$ ipython notebook
```

This will print some information about the notebook server in your console, and open a web browser to the URL of the web application (by default, http://127.0.0.1:8888).

The landing page of the IPython notebook web application, the dashboard, shows the notebooks currently available in the notebook directory (by default, the directory from which the notebook server was started).

You can create new notebooks from the dashboard with the New Notebook button, or open existing ones by clicking on their name.

At present, the recommended approach for Windows users is to run Ubuntu Linux 12.04 within a Virtual Machine and install the rmtk following the instructions above. Up-to-date Virtual-Box images containing the OpenQuake-engine and platform, and the Hazard and Risk Modeller's Toolkits are available here: <http://www.globalquakemodel.org/openquake/start/download/>

Knowledge of the Python programming language is not necessary in order to use the tools provided in the Risk Modeller's Toolkit. Nevertheless, a basic understanding of the data types and concepts of Python will come in handy if you are interested in modifying or enhancing the standard scripts provided in the toolkit. If you've never used Python before, the official [Python tutorial](#) is a good place to start. [A Byte of Python](#) is also a well-written guide to Python and a great reference for beginners. Appendix A at the end of this user manual also provides a quick-start guide to Python.

1.2 Current features

The Risk Modeller's Toolkit is currently divided into three modules:

Plotting tools: The plotting module of the RMTK provides scripts and notebooks for visualising all of the different hazard and risk outputs produced by calculations performed using the OpenQuake-engine. The visualisation tools currently support plotting of seismic hazard curves, uniform hazard spectra, hazard maps, loss exceedance curves, probabilistic loss maps, and damage distribution statistics, amongst others. This module also allow users to convert the different results from the standard OpenQuake XML format into other formats such as CSV.

Risk tools: This module provides useful scripts to post-process OpenQuake hazard and risk results and calculate further metrics.

Vulnerability tools: This module implements several methodologies for estimating fragility and vulnerability functions for individual buildings or for a class of buildings. The provided scripts differ in level of complexity of the methodology and according to the type of input data available for the buildings under study. The guidelines for analytical vulnerability assessment provided by the GEM Global Vulnerability Consortium have been used as the primary reference for the development of this module.

A summary of the methods available in the present version is given in Table 1.1.

Module	Feature	
Plotting Module	Hazard Curves

		SP-BELA
		Point Dispersion

Table 1.1 – Current features in the OpenQuake Risk Modeller's Toolkit

1.3 Organization

2. Plotting

The OpenQuake-engine is capable of generating several seismic hazard and risk outputs, such as loss exceedance curves, seismic hazard curves, loss and hazard maps, damage statistics, amongst others. Most of these outputs are stored using the Natural Risk Markup Language (NRML), or simple comma separated value (CSV) files. The Plotting module of the Risk Modeller's Toolkit allows users to visualize the majority of the OpenQuake-engine results, as well as to convert them into other formats compatible with GIS software (e.g. QGIS). Despite the default styling of the maps and curves defined within the Risk Modeller's Toolkit, it is important to state that any user can adjust the features of each output by modifying the original scripts.

2.1 Plotting damage distribution

Using the Scenario Damage Calculator (Silva et al., [2014a](#)) of the OpenQuake-engine, it is possible to assess the distribution of damage for a collection of assets considering a single seismic event. These results are comprised of damage per building typology, total damage distribution, and distribution of collapses in the region of interest.

2.1.1 Plotting damage distribution

This feature of the Plotting module allows users to plot the distribution of damage across the various vulnerability classes, as well as to the total damage distribution. For what concerns the former result, it is necessary to set the path to the output file using the parameter `tax_dmg_dist_file`. It is also possible to specify which vulnerability classes should be considered, using the parameter `taxonomy_list`. However, if a user wishes to consider all of the vulnerability classes, then this parameter should be left empty. It is also possible to specify if a 3D plot containing all of the vulnerability classes should be generated, or instead a 2D plot per vulnerability class. For follow the former option, the parameter `plot_3d` should be set to `True`. It is important to understand that this option leads to a plot of damage fractions for each vulnerability class, instead of the number of assets in each damage state. An example of this output is illustrated in Figure 2.1.

In order to plot the total damage distribution (considering the entire collection of assets), it is necessary to use the parameter `total_dmg_dist_file` to define the path to the respective output file. Figure 2.2 presents an example of this type of output.

Figure 2.1 – Damage disaggregation per vulnerability class.

Figure 2.2 – Total damage distribution.

2.1.2 Plotting collapse maps

The OpenQuake-engine also generates an output defining the spatial distribution of the mean (and associated standard deviation) of assets in the last damage state (usually representing collapse or complete damage). The location of this output needs to be specified using the parameter `collapse_map`. Then, it is necessary to specify whether the user desires a map with the aggregated number of collapses (i.e. at each location, the mean number of collapses across all of the vulnerability classes are summed) or a map for each vulnerability class. Thus, the following options are permitted:

1. Aggregated collapse map only.
2. Collapse maps per taxonomy only.
3. Both aggregated and taxonomy-based.

The plotting option should be specified using the parameter `plotting_type`, and the location of the exposure model used to perform the calculations must be defined using the variable `exposure_model`. A number of other parameters can also be adjusted to modify the style of the resulting collapse map as follows:

- `bounding_box`: If set to 0, the Plotting module will calculate the geographical distribution of the assets, and adjust the limits of the map accordingly. Alternatively, a user can also specify the minimum/maximum latitude and longitude that should be used in the creation of the map.

- `marker_size`: This attribute can be used to adjust the size of the markers in the map.
- `log_scale`: If set to `True`, it will apply a logarithmic scale on the color scheme of the map, potentially allowing a better visualization of the variation of the numbers of collapses in the region of interest.

An example of a collapse map is presented in Figure 2.3.

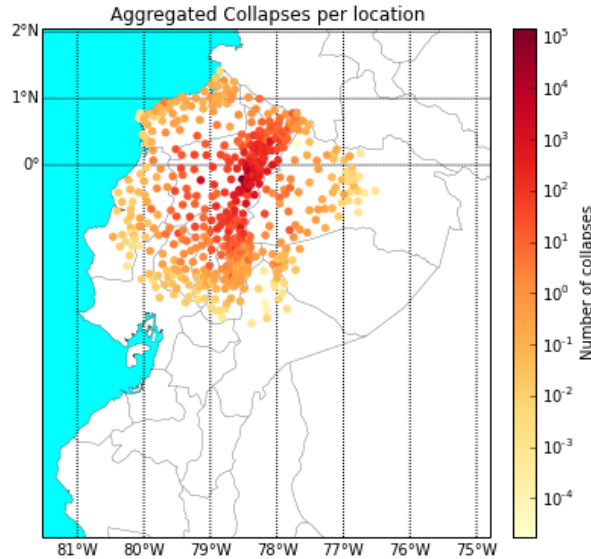

Figure 2.3 – *Spatial distribution of the mean number of collapses.*

2.2 Plotting hazard and loss curves

Using the Classical PSHA-based or Probabilistic Event-based Calculators (Silva et al., 2014a, Pagani et al., 2014) of the OpenQuake-engine, it is possible to calculate seismic hazard curves for a number of locations, or loss exceedance curves considering a collection of spatially distributed assets.

2.2.1 Plotting hazard curves and uniform hazard spectra

A seismic hazard curve defines the probability of exceeding a number of intensity measure levels (e.g. peak ground acceleration or spectral acceleration) for a given interval of time (e.g. 50 years). In order to plot these curves, it is necessary to define the path to the output file in the parameter `hazard_curve_file`. Then, since each output file might contain a great number of hazard curves, it is necessary to establish the location for each hazard curve will be extracted. To visualize the list of locations comprised in the output file, the function `hazard_curves.loc_list` can be employed. Then, the chosen location must be provided to the plotting function (e.g. `hazard_curves.plot("81.213823|29.761172")`). An example of a seismic hazard curve is provided in Figure 2.4.

To plot uniform hazard spectra (UHS), a similar approach should be followed. The output file containing the uniform hazard spectra should be defined using the parameter `uhs_file`, and then a location must be provided to the plotting function (e.g. `uhs.plot("81.213823|29.761172")`). An example of uniform hazard spectra is illustrated in Figure 2.5.

Figure 2.4 – Seismic hazard curve for peak ground acceleration (PGA).

Figure 2.5 – Uniform Hazard Spectra for a probability of exceedance of 10% in 50 years.

2.2.2 Plotting loss curves

A loss exceedance curve defines the relation between a set of loss levels and the corresponding probability of exceedance within a given time span (e.g. a year). In order to plot these curves, it is necessary to define the location of the output file using the parameter `loss_curves_file`. Since each output file may contains a large number of loss exceedance curves, it is necessary to define for which assets will the loss curves be extracted. The parameter `assets_list` should be employed to define all of the chosen asset ids. These ids can be visualize directly on the loss curve output file, or on the exposure model used for the risk calculations. It is also possible to define a logarithmic scale for the x and y axis using the parameters `log_scale_x` and `log_scale_y`. A loss exceedance curve for a single asset is depicted in Figure 2.6.

2.3 Plotting hazard and loss maps

The OpenQuake-engine offers the possibility of calculating seismic hazard and loss (or risk) maps. To do so, it utilizes the seismic hazard or loss exceedances curves, to estimate the

Figure 2.6 – *Loss exceedance curve.*

corresponding hazard or loss for the pre-defined return period (or probability of exceedance within a given interval of time).

2.3.1 Plotting hazard maps

A seismic hazard map provides the expected ground motion (e.g. peak ground acceleration or spectral acceleration) at each location, for a certain return period (or probability of exceedance within a given interval of time). To plot this type of maps, it is necessary to specify the location of the output file using the parameter `hazard_map_file`. An example hazard map is displayed in Figure 2.4.

Figure 2.7 – *Seismic hazard map for a probability of exceedance of 10% in 50 years.*

2.3.2 Plotting loss maps

A loss map provides the estimated losses for a collection of assets, for a certain return period (or probability of exceedance within a given interval of time). It is important to understand that these maps are not providing the distribution of losses for a seismic event for the chosen return period, nor the losses whose sum would correspond to the aggregated loss for the same return period. This type of maps is simply providing the expected loss for a specified level of frequency for each asset. To use this feature, it is necessary to define the path of the output file using the parameter `loss_map_file`, as well as the exposure model used to perform the risk

calculations through the parameter `exposure_model`. Then, similarly to what was explained in section 2.1.2 for collapse maps, it is possible to follow three approaches to generate the loss maps:

1. Aggregated loss map only.
2. Loss maps per taxonomy only.
3. Both aggregated and taxonomy-based.

Then, there are a number of options that can be used to modify the style of the maps. These include the size of the marker of the map (`marker_size`), the geographical limits of the map (`bounding_box`), and the employment of a logarithmic spacing for the color scheme (`log_scale`). An example loss map for a single vulnerability class is presented in Figure 2.8.

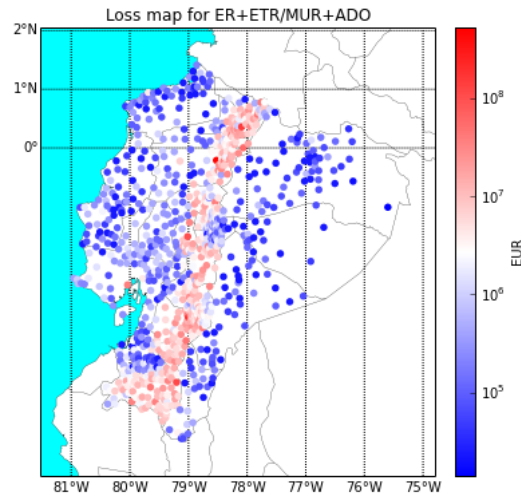

Figure 2.8 – Loss (economic) map for a probability of exceedance of 10% in 50 years.

As mentioned on the introductory section, it is also possible to convert any of the maps into a format (csv) easily readable by GIS software. To do so, it is necessary to set the parameter `export_map_to_csv` to `True`. As an example, a map containing the average annual losses for Ecuador has been converted to the csv format, and introduced into the QGIS software to produce the map presented in Figure 2.9.

Figure 2.9 – Average annual (economic) losses for Ecuador.

3. Risk

The OpenQuake-engine currently generates the most common seismic hazard and risk results (e.g. hazard maps, loss curves, average annual losses). However, it is recognized that there are a number of other metrics that might not be of interest of the general GEM community, but fundamental for specific users. This module of the Risk Modeller's Toolkit aims to provide users with additional risk results and functionalities.

3.1 Deriving Probable Maximum Losses (PML)

The Probabilistic Event-based Risk calculator (Silva et al., [2014a](#)) of the OpenQuake-engine is capable of calculating event loss tables, which contain a list of earthquake ruptures and associated losses. These losses may refer to specific assets, or the sum of the losses from the entire building portfolio (aggregated loss curves). Using this module, it is possible to derive a probable maximum loss (PML) curves (i.e. relation between a set of loss levels and corresponding return periods of exceedance), as illustrated in Figure 3.1.

Figure 3.1 – Probable Maximum Loss (PML) curve.

To use this feature, it is necessary to use the parameter `event_loss_table_folder` to

specify the location of the folder that contains the set of event loss tables and stochastic event sets. Then, it is also necessary to provide the total economic value of the building portfolio (using the variable `total_cost`) and the list of return periods of interest (using the variable `return_periods`). This module also offers the possibility of saving all of the information in csv files, which can be used in other software (e.g. Microsoft Excel) for other purposes. To do so, the parameters `save_elt_csv` and `save_ses_csv` should be set to `True`.

3.2 Selecting a logic tree branch

When a non-trivial logic-tree is used to capture the model uncertainty in the source model or in the choice of an appropriate ground motion prediction equation (GMPE) for each of the tectonic region types in the region considered, OpenQuake can calculate the hazard curves for each end-branch of the logic-tree individually. Now, if a risk modeller wishes to estimate damage or losses using one or a few of these branches only, it is useful to compare the hazard curves for the chosen branch with the mean hazard curve. Depending upon the distance of the hazard curve for a particular branch from the mean hazard curve, the risk modeller may wish to choose the branches for which the hazard curves are closest to the mean hazard curve. This Python script and corresponding IPython notebook allow the risk modeller to list the end-branches for the hazard calculation, sorted in increasing order of the distance of the branch hazard curve from the mean hazard curve. Currently, the distance metric used for performing the sorting is the root mean square distance.

4. Vulnerability

4.1 Introduction

4.2 Definition input models

To be completed by Anirudh.

4.2.1 Definition of capacity curves

To be completed by Anirudh.

4.2.2 Definition of ground motion records

The record-to-record variability is one of the most important sources of uncertainty in fragility assessment. In the Direct Nonlinear Static Procedures implemented in the Risk Modellers Toolkit (see Section 4.5), this source of uncertainty is directly introduced in the fragility estimates, based on previous nonlinear analyses. In the Record-based Nonlinear Static Procedures (Section ??) or in the Nonlinear Time History Analysis in Single Degree of Freedom Oscillators (Section 4.7), users have the possibility of introducing their own ground motion records. Each acceleration needs to be stored in a csv file (tabular format), as depicted in Table 4.1. This file format uses two columns, in which the first one contains the time (in seconds) and the second the corresponding acceleration (in g).

In order to load a set of ground motion records into the Risk Modellers Toolkit, it is necessary to import the module `utils`, and specify the location of the folder containing all of the ground motion records using the parameter `gmrs_folder`. Then, the collection of records can be loaded using the following command:

```
gmrs = utils.read_gmrs(gmrs_folder)
```

Once the ground motion records have been loaded, it is possible to calculate and plot the acceleration and displacement response spectra. To do so, it is necessary to specify the minimum and maximum period of vibration to be used in the calculations, using the variables `minT` and `maxT`, respectively. Then, the following command must be used:

Table 4.1 – Example of a ground motion record.

0.01	0.0211
0.02	0.0292
0.03	0.0338
0.04	0.0274
0.05	0.0233
0.06	0.0286
0.07	0.0292
0.08	0.0337
0.09	0.0297
0.1	0.0286
...	...

```
minT = 0.1
maxT = 2
utils.plot_response_spectra(gmrs,minT,maxT)
```

This will generate three plots: 1) spectral acceleration (in g) versus period of vibration (in sec); 2) spectral displacement (in m) versus period of vibration (in sec); and spectral acceleration (in g) versus spectral displacement (in m). Figure 4.1 illustrates the first two plots for a hundreds ground motion records.

Figure 4.1 – Response spectra in terms of spectral acceleration versus period of vibration (left) and spectral displacement versus period of vibration (right).

4.2.3 Definition of damage model

The derivation of fragility models requires the definition of a criterium to allocate one (or mutiple) structures in a set of damage states, according to their nonlinear structural response. These rules to relate structural response with physical damage can vary significantly across the literature. The displacement-based methodologies frequently adopt the strain on the concrete and

steel (e.g. Borzi et al., 2008b; Silva et al., 2013). The vast majority of the methodologies that require equivalent linearization methods or nonlinear time history analysis adopt interstorey drifts (e.g. Vamvatsikos and Cornell, 2005; Rossetto and Elnashai, 2005), or spectral displacement calculated based on a pushover curve (e.g. Erberik, 2008; Silva et al., 2014c). The various rules dictated by the damage model are currently being stored in a csv file (tabular format), as described below for each type of model.

Strain-based damage criterium

The displacement-based (Crowley et al., 2004) or mechanics-based (Borzi et al., 2008b) methodologies use strain levels to define a number of limit states. Thus, for each limit state, a strain for the concrete and steel should be provided. It is recognized that there is a large uncertainty in allocation of a structure into a physical damage state based on its structural response. Thus, the risk Modellers Toolkit allows the representation of the damage criterium in a probabilistic manner. This way, the parameter that establishes the damage threshold can be defined by a mean, a coefficient of variation and a probabilistic distribution (normal, lognormal or gamma) (Silva et al., 2013). This approach is commonly used to at least assess the spectral displacement at the yielding point (S_{dy}) and for the ultimate capacity (S_{du}). Other limit states can also be defined using other strain levels (e.g. Crowley et al., 2004), or a fraction of the yielding or ultimate displacement. For example, Borzi et al., 2008b defined light damage and collapse through the concrete and steel strains, and significant damage as $3/4$ of the ultimate displacement (S_{du}).

To use this damage criteria, it is necessary to define the parameter Type as `strain dependent` within the damage model file. Then, each limit state needs to be defined by a name (e.g. light damage), type of criterium and the adopted probabilistic model. Using the damage criteria described above (by Borzi et al., 2008b), an example of a damage model is provided in Table 4.2. In this case, the threshold for light damage is defined at the yielding point, which in return is calculated based on the yielding strain of the steel. The limit state for collapse is computed based on the mean strain in the concrete and steel (0.0075 and 0.0225, respectively) and the a coefficient of variation (0.3 and 0.45, respectively). The remaining limit state (significant damage), is defined as fraction (0.75) of the ultimate displacement (collapse).

Table 4.2 – *Example of a strain dependent damage model.*

Type	strain dependent			
Damage States	Criteria	distribution	mean	cov
light damage	S_{dy}	lognormal		0
significant damage	fraction S_{du}	lognormal	0.75	0
collapse	strain	lognormal	0.0075 0.0225	0.30 0.45

Capacity curve-based damage criterium

Several existing studies (e.g. Erberik, 2008; Silva et al., 2014c; Casotto et al., 2015) have relied on capacity curves (spectral displacement versus spectral acceleration) or pushover curves (roof displacement versus base shear) to define a set of damage thresholds. In the vast majority of these studies, the various limit states are defined as a function of the displacement at the yielding point (S_{dy}), the maximum spectral acceleration (or base shear), and/or of the ultimate displacement capacity (S_{du}). For this reason, the mechanism that has been implemented in the RMTK is considerably flexible, and allows users to define a set of limit states following the options below:

1. **fraction Sdy**: this limit state is defined as a fraction of the displacement at the yielding point (Sdy) (e.g. 0.75 of Sdy)
2. **Sdy**: this limit state is equal to the displacement at the yielding point, usually marking the initiation of structural damage.
3. **max Sa**: this limit state is defined at the displacement at the maximum spectral acceleration.
4. **mean Sdy Sdu**: this limit state is equal to the mean between the displacement at the yielding point (Sdy) and ultimate displacement capacity (Sdu).
5. **X Sdy Y Sdu**: this limit state is defined as the weighed mean between the displacement at the yielding point (Sdy) and ultimate displacement capacity (Sdu). X represents the weight associated with the former displacement, and Y corresponds to the weight of the latter (e.g. 1 Sdy 4 sdu).
6. **fraction Sdu**: this limit state is defined as a fraction of the ultimate displacement capacity (Sdu) (e.g. 0.75 of Sdu)
7. **Sdu**: this limit state is equal to ultimate displacement capacity (Sdu), usually marking the point beyond which structural collapse is assumed to occur.

In order to create a damage model based on this criterium, it is necessary to define the parameter Type as capacity curve dependent. Then, each limit state needs to be defined by a name (e.g. slight damage), type of criterium (as defined in the aforementioned list) and a potential probabilistic model (as described in the previous sub-section). An example of a damage model considering all of the possible options described in the previous list is presented in Table 4.3, and illustrated in Figure 4.2. Despite the inclusion of all of the options, a damage model using this approach may use only a few of these criteria. Moreover, some of the options (namely the first, fifth and sixth) may be used multiple times.

Table 4.3 – Example of a capacity curve dependent damage model.

Type	capacity curve dependent			
Damage States	Criteria	distribution	Mean	Cov
LS1	fraction Sdy	lognormal	0.75	0.0
LS2	Sdy	normal		0.0
LS3	max Sda	normal		0.0
LS4	mean Sdy Sdu	normal		0.0
LS5	1 Sdy 2 Sdu	normal		0.0
LS6	fraction Sdu	normal	0.85	0.0
LS7	Sdu	normal		0.0

Interstorey drift-based damage criterium

4.3 Model generator

To be completed by Vitor.

4.3.1 Generation of capacity curves using DBELA

The Displacement-based Earthquake Loss Assessment (DBELA) methodology permits the calculation of the displacement capacity of a collection of structures at a number of limit states (which could be structural or non-structural). These displacements are derived based on the capacity of an equivalent SDOF structure, following the principles of structural mechanics (Crowley et al., 2004; Bal et al., 2010; Silva et al., 2013).

Figure 4.2 – Representation of the possible options for the definition of the limit datates using a capacity curve.

The displacement at the height of the centre of seismic force of the original structure (H_{CSF}) can be estimated by multiplying the base rotation by the height of the equivalent SDOF structure (H_{SDOF}), which is obtained by multiplying the total height of the actual structure (H_T) by an effective height ratio (ef_h), as illustrated in Figure 4.3:

Figure 4.3 – Definition of effective height coefficient Glaister and Pinho, 2003.

Pinho et al., 2002 and Glaister and Pinho, 2003 proposed formulae for estimating the effective height coefficient for different response mechanisms. For what concerns the beam sway mechanism (or distributed plasticity mechanism, as shown in Figure 4.4), a ratio of 0.64 is proposed for structures with 4 or less storeys, and 0.44 for structures with 20 or more storeys. For any structures that might fall within these limits, linear interpolation should be employed. With regards to the column-sway mechanism (or concentrated plasticity mechanism, as shown in Figure 4.4), the deformed shapes vary from a linear profile (pre-yield) to a non-linear profile (post-yield). As described in Glaister and Pinho, 2003, a coefficient of 0.67 is assumed for the pre-yield response and the following simplified formula can be applied post-yield (to attempt to

account for the ductility dependence of the effective height post-yield coefficient):

$$ef_h = 0.67 - 0.17 \frac{\varepsilon_{s(LS_i)} - \varepsilon_y}{\varepsilon_{s(LS_i)}} \quad (4.1)$$

Figure 4.4 – Deformed profiles for beam-sway (left) and column-sway (right) mechanisms Paulay and Priestley, 1992.

The displacement capacity at different limit states (either at yield (δ_y) or post-yield ($\delta_{(LSi)}$) for bare frame or infilled reinforced concrete structures can be computed using simplified formulae, which are distinct if the structure is expected to exhibit a beam- or column-sway failure mechanism. These formulae can be found in Bal et al., 2010 or Silva et al., 2013, and their mathematical formulation is described in detail in Crowley et al., 2004.

In order to estimate whether a given frame will respond with a beam- or a column-sway mechanism it is necessary to evaluate the properties of the storey. A deformation-based index (R) has been proposed by Abo El Ezz, 2008 which reflects the relation between the stiffness of the beams and columns. This index can be computed using the following formula:

$$R = \frac{h_b / l_b}{h_c / l_c} \quad (4.2)$$

Where l_c stands for the column length. Abo El Ezz, 2008 proposed some limits for this index applicable to bare and fully infilled frame structures, as described in Table 4.4.

Table 4.4 – Limits for the deformation-based sway index proposed by Abo El Ezz, 2008

Building Typology	Beam sway	Column sway
Bare frames	$R \leq 1.0$	$R > 1.5$
Fully infilled frames	$R \leq 1.0$	$R > 1.0$

The calculation of the corresponding spectral acceleration is performed by assuming a perfectly elasto-plastic behaviour. Thus, the spectral displacement for the yielding point is used to derive

the associated acceleration through the following formula:

$$Sa_i = \frac{4\pi^2 Sd_i}{T_y^2} \quad (4.3)$$

Where T_y stands for the yielding period which can be calculated using simplified formulae (e.g. Crowley and Pinho, 2004; Crowley and Pinho, 2006), as further explained in Section 4.6.6. Due to the assumption of the elasto-plastic behaviour, the spectral acceleration for the remaining limit states (or spectral displacements) will be the same (see Figure 4.5).

In order to use this methodology it is necessary to define a building model, which specifies the probabilistic distribution of the geometrical and material properties. This information is currently stored in a *csv* file (tabular format), as presented in Table 4.6.

Table 4.5 – *Example of a building model compatible with the DBELA method.*

Structure type	bare frame				
ductility	ductile				
number of storeys	3				
steel modulus	lognormal	210000	0.01	0	inf
steel yield strength	normal	371.33	0.24	0	inf
ground floor height	discrete	2.8 3.1 3.2	0.48 0.15 0.37	0	inf
regular floor height	lognormal	2.84	0.08	0	inf
column depth	lognormal	0.45	0.12	0.3	0.6
beam length	gamma	3.37	0.38	0	inf
beam depth	lognormal	0.6	0.16	0.4	0.8

The `structure type` can be set to `bare frame` or `infilled frame`, while the parameter `ductility` can be equal to `ductile` or `non-ductile`. The variable `number of storeys` must be equal to an integer defining the number of floors of the building class. The following parameters (`steel modulus`, `steel yield strength`, `ground floor height`, `regular floor height`, `column depth`, `beam length`, `beam depth`) define the represent the geometrical and material properties of the building class, and can be defined in a probabilistic manner. Currently, three parametric statistical models have been implemented (`normal`, `lognormal` and `gamma`), as well as discrete (i.e. probability mass function) model (`discrete`). The model that should be used must be specified on the second column. Then, for the former type of models (parametric), the mean and coefficient of variation should be provided in the third and forth columns, respectively. For the discrete model, the central values of the bins and corresponding probabilities of occurrence should be defined in the third and forth columns, respectively. The last two columns can be used to truncate the probabilistic distribution between a minimum (fifth column) and maximum (sixth column) values. In order to define a parameter in a deterministic manner (no variability), the coefficient of variation for the associated attribute can be set to zero, and the same value (mean) will be used repeatedly.

The location of the building model and the damage model (see Section 4.2.3) should be specified in the variables `building_model` and `damage_model`, respectively. The number of capacity curves that should be generated must be defined using the parameter `no_assets`. Then, after importing the module `DBELA`, the set of capacity curves can be generated using the following commands:

```

building_class_model = DBELA.read_building_class_model(building_model)
assets = DBELA.generate_assets(building_class_model,no_assets)
capacity_curves = DBELA.generate_capacity_curves(assets,damage_model)

```

The first function (`read_building_class_model`) processes the information about the building class; the second function (`generate_assets`) uses a Monte Carlo sampling process to generate a set of synthetic structural models (each one with unique geometrical and material properties); and the final function (`generate_capacity_curves`) combines the generated assets with the damage model to calculate a capacity curve per structure. Figure 4.5 presents a collection of capacity curves generated using this methodology.

Figure 4.5 – Capacity curves for reinforced concrete bare frames generated using the DBELA methodology.

4.3.2 Generation of capacity curves using SP-BELA

The Simplified Pushover-based Earthquake Loss Assessment methodology (Borzi et al., 2008b) allows the calculation of the displacement capacity (i.e. spectral displacement) and collapse multiplier (i.e. spectral acceleration) using a mechanics-based procedure, similar to what has been proposed by Cosenza et al., 2005. The methodology currently implemented in the Risk Modellers Toolkit only supports reinforced concrete frames, though a similar process has been proposed for masonry structures (Borzi et al., 2008a).

The original methodology (as proposed by Borzi et al., 2008b) considered three limit states (light damage (corresponding to the yielding point), significant damage, and collapse). However, other limit states can be considered, granted that the user provides the information required to establish each limit state.

The spectral displacement at each limit state is calculated by firstly assessing the expected chord rotation at the associated damage threshold, and then multiplying this rotation by the height of the equivalent single degree of freedom (SDOF) system. The rotation at the yielding point (Θ_y) can be calculated using the formula below, as proposed by Cosenza et al., 2005 and

Panagiotakos and Fardis, 2001:

$$\Theta_y = \phi_y \frac{L_V}{3} + 0.0013 \left(1 + 1.5 \frac{h}{L_V} \right) + 0.13 \phi_y \frac{d_b f_y}{\sqrt{f_c}} \quad (4.4)$$

Where ϕ_y stands for the yield curvature of the section, L_V represents the shear span (which for columns can be assumed as half of the interstorey height (Borzi et al., 2008b)), h stands for the section height, d_b is the longitudinal bar diameter, and f_y and f_c are the strength of the steel and concrete (in MPa), respectively. The yield curvature (ϕ_y) can be calculated using the equation proposed by Priestley et al., 2007:

$$\phi_y = 2.14 \frac{\varepsilon_y}{h} \quad (4.5)$$

Where ε_y represents the yield strain of the longitudinal rebars.

For what concerns the ultimate rotation capacity (Θ_u), Panagiotakos and Fardis, 2001 proposed the following formula:

$$\Theta_u = \frac{1}{\gamma_{el}} \left[\Theta_y + (\phi_u - \phi_y) L_{pl} \left(1 - \frac{0.5 L_{pl}}{L_V} \right) \right] \quad (4.6)$$

Where γ_{el} is 1.5 for the primary structural elements and 1 for all others (Borzi et al., 2008b), ϕ_u stands for the ultimate curvature, and L_{pl} is the plastic hinge length, which can be computed through the following equation:

$$\phi_u = \frac{\varepsilon_{cu} + \varepsilon_{su}}{h} \quad (4.7)$$

Where ε_{cu} and ε_{su} are the ultimate concrete and steel strain, respectively. These two parameters depend on the level of confinement of the reinforced concrete and expected ductility, and reasonable ranges can be found in Calvi, 1999, Crowley et al., 2004 or Bal et al., 2010.

Other rotation thresholds (corresponding to other limit states) can also be calculated, either through the definition of concrete and steel strains (e.g. Crowley et al., 2004), or as a fraction of the previously described rotations. For example, Borzi et al., 2008b defined the limit state for significant damage as $3/4$ of the ultimate rotation capacity (Θ_u).

As previously mentioned, the spectral displacement at each limit state can be calculated by multiplying the respective rotation by the height of the equivalent SDOF system. This height is calculated by multiplying the total height of the structure (H_T) by an effective height ratio (ef_h). The calculation of this ratio depends on the expected failure mechanism (beam sway or column sway - see Figure 4.4), and its calculation has been explained in Section 4.3.1. For the yielding point, the spectral displacement can then be calculated as follows:

$$\Delta_y = \Theta_y ef_h H_T \quad (4.8)$$

The displacement capacity at the remaining limit states depends on the expected failure mechanisms (as defined in Figure 4.4), and can be calculated using the following formulae:

For beam sway:

$$\Delta_{LS_i} = \Delta_y + (\Theta_{LS_i} - \Theta_y) e f_h H_T \quad (4.9)$$

for column sway:

$$\Delta_{LS_i} = \Delta_y + (\Theta_{LS_i} - \Theta_y) h_p \quad (4.10)$$

Where h_p stands for the ground storey height.

The calculation of the spectral acceleration for each limit states follows the same procedure explained in the previous Section, in which an elasto-plastic behaviour is assumed, and the following formula is employed to calculate acceleration at the yielding point:

$$S a_i = \frac{4\pi^2 S d_i}{T_y^2} \quad (4.11)$$

Where T_y stands for the yielding period which can be calculated using simplified formulae (e.g. Crowley and Pinho, 2004; Crowley and Pinho, 2006), as further explained in Section 4.6.6.

To use this methodology it is necessary to define a building model, which specifies the probabilistic distribution of the geometrical and material properties. This information is currently stored in a *csv* file (tabular format), as presented in Table 4.6.

Table 4.6 – Example of a building model compatible with the SPBELA method.

Structure type	bare frame				
ductility	ductile				
number of storeys	3				
steel modulus	lognormal	210000	0.01	0	inf
concrete strength	normal	30	0.05	0	inf
steel bar diameter	discrete	0.01	1	0	inf
steel yield strength	normal	371.33	0.24	0	inf
ground floor height	discrete	2.8 3.1 3.2	0.48 0.15 0.37	0	inf
regular floor height	lognormal	2.84	0.08	0	inf
column depth	lognormal	0.45	0.12	0.3	0.6
beam length	gamma	3.37	0.38	0	inf
beam depth	lognormal	0.6	0.16	0.4	0.8

The definition of each parameter follows the same approach described in the previous Section for the Displacement-based Earthquake Loss Assessment (DBELA) methodology.

The location of the building model and the damage model (see Section 4.2.3) should be specified in the variables `building_model` and `damage_model`, respectively. The number of capacity curves that should be generated must be defined using the parameter `no_assets`. Then, after importing the module SPBELA, the set of capacity curves can be generated using the following commands:

```
building_class_model = SPBELA.read_building_class_model(building_model)
assets = SPBELA.generate_assets(building_class_model,no_assets)
capacity_curves = SPBELA.generate_capacity_curves(assets,damage_model)
```

The first function (`read_building_class_model`) processes the information about the building class; the second function (`generate_assets`) uses a Monte Carlo sampling process to generate a set of synthetic structural models (each one with unique geometrical and material properties); and the final function (`generate_capacity_curves`) combines the generated assets with the damage model to calculate a capacity curve per structure. Figure 4.6 presents a collection of capacity curves generated using this methodology.

Figure 4.6 – Capacity curves for reinforced concrete bare frames generated using the SPBELA methodology.

4.3.3 Generation of capacity curves using point dispersion

This module of the Risk Modellers Toolkit allows the generation of a large number of capacity curves, based on a single median curve, and information regarding the expected dispersion at each point of the curve.

As an example, in a study carried out by Silva et al., [2014b](#), several capacity curves were derived for 100 reinforced concrete frames with 4 storeys and without seismic provisions, as illustrated in Figure 4.7. In addition to the mean and median capacity curves, an additional capacity curve was also derived using the mean geometrical and material properties of the building class of interest. From this distribution of curves, it is possible to assess the probabilistic distribution of a number of specific points, such as the yielding or ultimate capacities. Then, once adequate statistical models have been defined for these specific points, it is possible to reproduce the the distribution of capacity curves using a Monte Carlo approach. If one assumes that such distribution could be applicable to other building classes, then it is possible to produce sets of capacity curves (as a way to propagate the building-to-building variability), based on this dispersion and a capacity curve believed to be representative of the median capacity of the building class.

To use this methodology, it is necessary to import the module `point_dispersion`. Then, the spectral acceleration and displacement of the median capacity curve should be defined in the vectors `Sa` and `Sd`, respectively. For each point in these vectors, it is necessary to provide the corresponding variability (as a form of a coefficient of variation), in the variables `Sa_cov` and `Sd_cov`. The type of probabilistic distribution that should be used must be defined using the parameter `type_of_dist`. Currently this module allows `normal` and `lognormal`. An example of the definition of these variables is provided below. In this case, the capacity curves are being defined using three points (the yielding capacity, the point of maximum force and the ultimate displacement).

Figure 4.7 – Capacity curves using a displacement-based adaptive pushover approach (Silva et al., 2014b).

```
Sa = [0.25, 0.45, 0.35]
Sa_cov = [0.25, 0.30, 0.30]
Sd = [0.10, 0.20, 0.50]
Sd_cov = [0.20, 0.30, 0.45]
type_dist = 'normal'
```

Within this methodology, it is also possible to specify the correlation in the spectral acceleration (Sa_corr) and spectral displacement (Sd_corr). If these correlation factors are set to zero, then the sampling process is carried out independently. On the other hand, if these parameters are set to one, then a full correlation is assumed, which means, for example, if a higher displacement is sampled for the yielding point, then a large displacement will also be sampled for the remaining points. Values between zero and one will lead to intermediate situations. It is also possible to control the correlation between the spectral acceleration and displacement, using the variable $SaSd_corr$. The dispersion of the synthetic capacity curves can also be controlled through the allowed number of standard deviations above or below the median capacity curve. This aspect is controlled by the parameter $truncation$, which should be equal to the maximum number of allowed standard deviations. For example, a value equal to 1 signifies that all of the generated capacity curves will be within one standard deviation of the median capacity curve. Finally, the number of capacity curves that will be generated needs to be specified using the variable no_cc . Figure 4.8 illustrates 100 capacity curves generated using the data provided above.

4.4 Conversion from MDOF to SDOF

Several structural analysis packages allow the user to perform a reliable pushover analysis on a nonlinear model of the MDOF structure. Often, these MDOF pushover curves need to be converted to simplified SDOF models for use in nonlinear static analysis methods. This module allows the conversion of the MDOF results into 'equivalent SDOF' results, thus making them compatible with a wide range of non-linear static procedures. At present, two methods are provided in this module for obtaining equivalent SDOF capacity curves for an MDOF system.

Figure 4.8 – Capacity curves generated using the point dispersion approach.

4.4.1 Conversion based on one mode of vibration

This method allows the user to convert a pushover curve for an MDOF system into an equivalent SDOF capacity curve, considering the first mode of vibration only. The supplied pushover curve, which is in terms of base shear and roof displacement, is transformed into an equivalent SDOF capacity curve, which is in terms of spectral acceleration and spectral displacement. The properties of the equivalent SDOF model correspond to the properties of the first mode of vibration of the MDOF system. The roof displacement is converted to S_d by normalising by the participation factor of the first mode of vibration, whereas the base shear is normalised to give S_a using the the participation factor and modal mass for the first mode.

4.4.2 Conversion using an adaptive approach

Adaptive pushover methods have the advantage of better accounting for stiffness degradation, influence of higher mode effects, and spectral amplifications because of ground motion frequency content. In this method, instead of applying an invariant load vector, the structural properties of the model are evaluated at each step of the analysis, and the loading pattern is updated accordingly. In this way, the variation in the structural stiffness at different deformation levels, and consequently the system degradation and period elongation can be accounted for. The only apparent drawback of this methodology can be the additional computation time required to assess the structural characteristics at every step.

The equivalent system displacement $\Delta_{sys,k}$ at step k is calculated as:

$$\Delta_{sys,k} = \frac{\sum_i m_i \Delta_{i,k}^2}{\sum_i m_i \Delta_{i,k}} \quad (4.12)$$

Note that $\Delta_{sys,k}$ is defined to be the inverse of the modal participation factor.

The equivalent system acceleration $S_{a-cap,k}$ at step k is calculated as:

$$S_{a-cap,k} = \frac{V_{b,k}}{M_{sys,k}g} \quad (4.13)$$

The equivalent system mass $M_{sys,k}$ is defined as:

$$M_{sys,k} = \frac{\sum_i m_i \Delta_{i,k}}{M_{sys,k}g} \quad (4.14)$$

Note that $M_{sys,k}$ is the modal mass of the system at analysis step k .

4.5 Direct nonlinear static procedures

Ruiz-Garcia and Miranda (2007), Vamvatsikos and Cornell (2006) and Dolsek and Fajfar (2004) studies on the assessment of nonlinear structural response, have been integrated in three nonlinear static procedures, which are based on the use of capacity curves, resulting from nonlinear static pushover analysis, to determine directly the median seismic intensity values \hat{S}_a corresponding to the attainment of a certain damage state threshold (limit state) and the corresponding dispersion β_{S_a} . These parameters are used to represent a fragility curve as the probability of the limit state capacity C being exceeded by the demand D , both expressed in terms of intensity levels (S_a, ds and S_a respectively), as shown in the following equation:

$$P_{LS}(S_a) = P(C < D|S_a) = \Phi\left(\frac{\ln S_a - \ln \hat{S}_a}{\beta_{S_a}}\right) \quad (4.15)$$

The methodologies implemented allow to consider different shapes of the pushover curve, multilinear and bilinear, record-to-record dispersion and dispersion in the damage state thresholds in a systematic and harmonised way.

The intensity measure to be used is S_a and a mapping between any engineering demand parameter (EDP), assumed to describe the damage state thresholds, and the roof displacement should be available from the pushover analysis.

The methodologies are originally built for single building fragility curves, however the fragility curves derived for single buildings can be combined in a unique fragility curve, which considers also the inter-building uncertainty, as described in the Section 4.5.1.

4.5.1 SPO2IDA (Vamvatsikos and Cornell 2006)

The tool spo2ida (Vamvatsikos and Cornell, 2005) is capable of converting static pushover curves into 16%, 50% and 84% ida curves, as shown in Figure 4.9, using empirical relationships from a large database of incremental dynamic analysis results.

Figure 4.9 – spo2ida tool: IDA curves derived from Pushover curve.

The spo2ida tool is applicable to any kind of multi-linear capacity curve. Making use of this tool is possible to estimate single building fragility curve and fragility curves derived for single buildings can be combined in a unique fragility curve, which considers also the inter-building

uncertainty.

Given an idealised capacity curve the spo2ida tool uses an implicit R - μ - T relation to correlate nonlinear displacement, expressed in terms of ductility μ to the corresponding median capacities in terms of the parameters R . R is the lateral strength ratio, defined as the ratio between the spectral acceleration S_a and the yielding capacity of the system S_{ay} . Each branch of the capacity curve, hardening, softening and residual plateau, is converted to a corresponding branch of the three ida curves, using the R - μ - T relation, which is a function of the hardening stiffness, the softening stiffness and the residual force. These parameters are derived from the idealised pushover capacity expressed in μ - R terms, as well as the ductility levels at the onset of each branch. If some of the branches of the pushover curve are missing because of the seismic behaviour of the system, spo2ida can equally work with bilinear, trilinear and quadrilinear idealisations.

The result of the spo2ida routine is thus a list of ductility levels and corresponding R values at 50%, 16% and 84% percentiles. For any inelastic displacement, and therefore any level of ductility μ the corresponding $R_{50\%}$, $R_{16\%}$, and $R_{84\%}$ values are found interpolating the aforementioned ida curves. Median R and its dispersion at ductility levels corresponding to the damage thresholds d_s can thus be determined, and converted into median S_{a,d_s} and its dispersion due to record-to-record variability $\beta_{S_{ad}}$ according to equations 4.16 and 4.17.

$$\hat{S}_{a,d_s} = R_{50\%}(\mu_{d_s})S_{ay} \quad (4.16)$$

$$\beta_{S_{ad}} = \beta_{R(\mu_{d_s})} = \frac{\ln R(\mu_{d_s})_{84\%} - \ln R(\mu_{d_s})_{16\%}}{2} \quad (4.17)$$

If dispersion due to uncertainty in the limit state definition β_{θ_c} is different from zero a Monte Carlo sampling needs to be performed to combine it with the record-to-record dispersion. Different values of ductility limit state are sampled from the lognormal distribution with median the median value of the ductility limit state, and dispersion the input β_{θ_c} . For each of these ductilities the corresponding median $R_{50\%}$ and $R_{16\%}$, $R_{84\%}$ are found and converted into \hat{S}_{a,d_s} and $\beta_{S_{ad}}$ according to equation 4.16 and 4.17. MC random S_a for each MC sampled ductility limit state are computed, and their median and the dispersion are estimated. These parameters constitute the median \hat{S}_{a,d_s} and the total dispersion β_{S_a} for the considered damage state. The procedure is repeated for each damage state.

Multiple-Building Fragility and Vulnerability function

If multiple buildings have been input to derive fragility function for a class of buildings all $\hat{S}_{a,blg}$ and $\beta_{S_{a,blg}}$ are combined in a single lognormal curve. A minimum of 5 buildings should be considered to obtain reliable results for the class.

A new issue arises when multiple buildings are considered: the S_a at the fundamental period of each building should be converted to a common intensity measure, to be able to combine the different fragility functions. A common intensity measure is selected to be S_a at the period T_{av} , which is a weighted average of the individual building fundamental periods T_1 . Then each individual fragility needs to be expressed in terms of the common $S_a(T_{av})$, using a spectrum. FEMA P-695 (ATC-63, 2007) far field set of 44 accelerograms (22 records for the two directions) was used to derive a mean uniform hazard spectrum, and the ratio between the S_a at different periods is used to scale the fragility functions. It can be noted that the actual values of the

spectrum are not important, but just the spectral shape. The median \hat{S}_a is converted to the mean $\mu_{\ln(S_a)}$ of the corresponding normal distribution ($\mu_{\ln(S_a)} = \ln(\hat{S}_a)$) and simply scaled to the common intensity measure as follows:

$$\mu_{\ln(S_a),blg} = \mu_{\ln(S_a),blg} S(T_{av})/S(T_{1,blg}) \quad (4.18)$$

$$\beta_{S_a,blg} = \beta_{S_a,blg} S(T_{av})/S(T_{1,blg}) \quad (4.19)$$

where $S(T_{av})/S(T_{1,blg})$ is defined as spectral ratio. Finally the parameters of the single lognormal curve for the class of buildings, mean and dispersion, can be computed as the weighted mean of the single means and the weighted SRSS of the inter-building and intra-building standard deviation, the standard deviation of the single means and the single dispersions respectively, as shown in the following equations:

$$\mu_{\ln(S_a),tot} = \sum_{i=0}^{n.blg} w_{blg-i} \mu_{\ln(S_a),blg-i} \quad (4.20)$$

$$\beta_{S_a,tot} = \sqrt{\sum_{i=0}^{n.blg} w_{blg-i} ((\mu_{\ln(S_a),blg-i} - \mu_{\ln(S_a),tot})^2 + \beta_{S_a,blg-i}^2)} \quad (4.21)$$

In order to use this methodology, it is necessary to load one or multiple capacity curves as described in Section 4.2.1. It is also necessary to specify the type of shape the capacity curves want to be idealised with, using the parameter `idealised_type` (either `bilinear` or `quadrilinear`). If the user has already at disposal an idealised multilinear pushover curve for each building, the variable `Idealised` in the csv input file should be set to `TRUE`, and idealised curves should be provided according to what described in section 4.2.1. Then, it is necessary to specify a damage model using the parameter `damage_model` (see Section 4.2.3).

If dispersion due to uncertainty in the limit state definition is different from zero a Monte Carlo sampling needs to be performed to combine it with the record-to-record dispersion. The number of Monte Carlo samples should be defined in the variable `montecarlo_samples`. After importing the module `SP02IDA_procedure`, it is possible to calculate the parameter of the fragility model, median and dispersion, using the following command:

```
fragility_model = SP02IDA_procedure.calculate_fragility(capacity_curves,
... idealised_capacity, damage_model, montecarlo_samples, Sa_ratios,
... ida_plotflag)
```

where `Sa_ratios` is the spectral ratio variable needed to combine together fragility curves for many buildings, as described in Section 4.8.1, and `ida_plotflag` indicates whether `ida` plots want to be displayed (`ida_plotflag = 1`) or not (`ida_plotflag = 0`).

4.5.2 Dolsek and Fajfar 2004

This procedure by (Dolsek and Fajfar, 2004) provides a simple relationship between inelastic displacement of a SDoF system and the corresponding median elastic spectral displacement value. The procedure presented herein is applicable to any kind of multi-linear capacity curve and it can be used to estimate single building fragility curve. Moreover the fragility curves derived for single buildings can be combined in a unique fragility curve, which considers also the inter-building uncertainty.

The relationship provided by (Dolsek and Fajfar, 2004) has been adapted for MDoF systems, relating the inelastic top displacement of a structure \hat{d}_{roof} to the median elastic spectral acceleration value at its fundamental period of vibration $\hat{S}_a(T_1)$, as presented in the following equation:

$$\hat{S}_a(T_1) = \frac{4\pi^2}{\hat{C}_R T^2 \Gamma_1 \Phi_1} \hat{d}_{roof} \quad (4.22)$$

where $\Gamma_1 \Phi_1$ is the first mode participation factor estimated for the first-mode shape normalised by the roof displacement. The value of C_R , the ratio between the inelastic and the elastic spectral displacement, is found from the following equation:

$$\hat{C}_R = \frac{\mu}{R(\mu)} \quad (4.23)$$

where μ and R are the median values of ductility level and the reduction factor for that level of ductility respectively. R is defined as the ratio between the spectral acceleration S_a and the yielding capacity of the system S_{ay} . According to the results of an extensive parametric study using three different sets of recorded and semi-artificial ground motions, (Dolsek and Fajfar, 2004) related the ductility demand μ and reduction factor R through the following formula:

$$\mu = \frac{1}{c}(R - R_0) + \mu_0 \quad (4.24)$$

In the proposed model μ is linearly dependent on R within two reduction factor intervals. The parameter c defines the slope of the R - μ relation, and it depends on the idealised pushover curve parameters (the initial period of the system T , the maximum to residual strength ratio r_u , the ductility at the onset of degradation μ_s) and the corner periods T_c and T_d . T_c and T_d are the corner periods between the constant acceleration and constant velocity part of the idealised elastic spectrum, and between the constant velocity and constant displacement part of the idealised elastic spectrum respectively. R_0 and μ_0 are the values of R and μ on the capacity curve corresponding to the onset of hardening or softening behaviour, according to the following relationship:

$$\mu_0 = 1 \dots \text{if } R \leq R(\mu_s); \mu_0 = \mu_s \dots \text{if } R > R(\mu_s) \quad (4.25)$$

$$R_0 = 1 \dots \text{if } R \leq R(\mu_s); R_0 = R(\mu_s) \dots \text{if } R > R(\mu_s) \quad (4.26)$$

Given the parameters of the multilinear pushover curves (R_0 , μ_0 , r_u , μ_s) and T , the median R - μ curve can be constructed using the aforementioned relationship, as presented in the following Figure.

Figure 4.10 – R - μ curves derived from Pushover curve.

The relationship between the 16th and 84th fractiles of μ and R_{50} needs to be derived using the equations from (Ruiz-Garcia and Miranda, 2007) instead, given that (Dolsek and Fajfar, 2004) do not provide estimates of the dispersion of R . This is done by computing the value of record-to-record dispersion in terms of top displacement $\beta_{\theta d}$ for a number of R with eq. 4.33, and calculating the 16th and 84th fractiles of μ ($\mu_{16\%}$ and $\mu_{84\%}$), according to the Equations 4.27 and 4.28. The $\mu_{50\%} - R_{50\%}$, $\mu_{16\%} - R_{50\%}$ and $\mu_{84\%} - R_{50\%}$ curves can thus be drawn, as shown in Figure 4.11.

Figure 4.11 – $\mu_{50\%} - R_{50\%}$, $\mu_{16\%} - R_{50\%}$ and $\mu_{84\%} - R_{50\%}$ curves

$$\mu_{ds,16} = \hat{\mu}_{ds} e^{-\beta_{\theta d,ds}} \quad (4.27)$$

$$\mu_{ds,84} = \hat{\mu}_{ds} e^{\beta_{\theta d,ds}} \quad (4.28)$$

For any inelastic displacement, and therefore any level of ductility μ the corresponding $R_{50\%}$, $R_{16\%}$, and $R_{84\%}$ values are found interpolating the aforementioned curves. Median R and its dispersion at ductility levels corresponding to the damage thresholds ds can thus be determined, and converted into median $S_{a,ds}$ and its dispersion due to record-to-record variability $\beta_{S_{ad}}$ according to equations 4.16 and 4.17.

If dispersion in the damage state threshold is different from zero, different values of ductility limit state are sampled from the lognormal distribution with median the median value of the

ductility limit state, and dispersion the input $\beta_{\theta c}$. For each of these ductilities the corresponding $R_{50\%}$, $R_{16\%}$, and $R_{84\%}$ values are found interpolating the $\mu_{50\%} - R_{50\%}$, $\mu_{16\%} - R_{50\%}$ and $\mu_{84\%} - R_{50\%}$ curves, and converted into $\hat{S}_{a,ds}$ and $\beta_{S_{ad}}$ according to Equations 4.16 and 4.17. MC random S_a for each of the MC sampled ductility limit states are computed using $\hat{S}_{a,ds}$ and $\beta_{S_{ad}}$, and their median and dispersion are estimated. These parameters constitute the median $\hat{S}_{a,ds}$ and the total dispersion β_{S_a} for the considered damage state. The procedure is repeated for each damage state.

If multiple buildings have been input to derive fragility function for a class of buildings all $\hat{S}_{a,blg}$ and $\beta_{S_{a,blg}}$ are combined in a single lognormal curve as described in section 4.5.1.

In order to use this methodology, it is necessary to load one or multiple capacity curves as described in Section 4.2.1. The capacity curves are then idealised with a bilinear elasto-plastic shape. It is also necessary to specify the type of shape the capacity curves want to be idealised with, using the parameter `idealised_type` (either `bilinear` or `quadrilinear`). If the user has already at disposal an idealised multilinear pushover curve for each building, the variable `Idealised` in the csv input file should be set to `TRUE`, and idealised curves should be provided according to what described in section 4.2.1. Then, it is necessary to specify a damage model using the parameter `damage_model` (see Section 4.2.3).

If dispersion due to uncertainty in the limit state definition is different from zero a Monte Carlo sampling needs to be performed to combine it with the record-to-record dispersion. The number of Monte Carlo samples should be defined in the variable `montecarlo_samples`. After importing the module `DF2004`, it is possible to calculate the parameter of the fragility model, median and dispersion, using the following command:

```
fragility_model = DF2004.calculate_fragility(capacity_curves, ...
idealised_capacity, damage_model, montecarlo_samples, Sa_ratios, ...
corner_periods)
```

where `Sa_ratios` is a variable needed to combine together fragility curves for many buildings, as described in Section 4.5.1.

4.5.3 Ruiz Garcia and Miranda 2007

The research by (Ruiz-Garcia and Miranda, 2007) provides a simple relationship for SDoF systems between inelastic displacement and the corresponding median elastic spectral displacement value. The procedure presented herein is applicable to bilinear elasto-plastic capacity curve only and it can be used to estimate single building fragility curve. Moreover the fragility curves derived for single buildings can be combined in a unique fragility curve, which considers also the inter-building uncertainty.

The relationship provided by (Ruiz-Garcia and Miranda, 2007) has been adapted for MDoF systems ((Vamvatsikos, 2014)), relating the inelastic top displacement of a structure \hat{d}_{roof} to the median elastic spectral displacement value at its fundamental period of vibration $\hat{S}_d(T)$, as presented in the following equation:

$$\hat{S}_d(T_1) = \frac{\hat{d}_{roof}}{\hat{C}_R \Gamma_1 \Phi_1} \quad (4.29)$$

where $\Gamma_1 \Phi_1$ is the first mode participation factor estimated for the first-mode shape normalised by the roof displacement, and C_R is the inelastic displacement ratio (inelastic over

elastic spectral displacement), computed by (Ruiz-Garcia and Miranda, 2007) for nonlinear SDoF systems, which is a function of the first-mode period of vibration and the relative lateral strength of the system R . Therefore the median spectral acceleration at the fundamental period of vibration $\hat{S}_a(T)$ turns out to be expressed as a function of top displacement according to the following equation:

$$\hat{S}_a(T) = \frac{4\pi^2}{\hat{C}_R T^2 \Gamma_1 \Phi_1} \hat{d}_{roof} \quad (4.30)$$

Estimates of \hat{C}_R parameter are provided by (Ruiz-Garcia and Miranda, 2007), as result of nonlinear regression analysis of three different measures of central tendency computed from 240 ground motions:

$$\hat{C}_R = 1 + \frac{\hat{R} - 1}{79.12 T_1^{1.98}} \quad (4.31)$$

where \hat{R} is given by the following equation:

$$\hat{R} = \max(0.425(1 - c + \sqrt{c^2 + 2c(2\hat{\mu} - 1) + 1}), 1) \quad (4.32)$$

where $c = 79.12 T_1^{1.98}$, and $\hat{\mu}$ is the median ductility level of interest.

Moreover (Ruiz-Garcia and Miranda, 2007) provide an estimate of the dispersion of C_R parameter due to record-to-record variability with Equation 4.33, that can be assumed equal to the dispersion of d_{roof} , since the two quantities are proportional.

$$\sigma_{\ln(C_R)} = \sigma_{\ln(d_{roof})} = \beta_{\theta d} = 1.975 \left[\frac{1}{5.876} + \frac{1}{11.749(T + 0.1)} \right] [1 - \exp(-0.739(R - 1))] \quad (4.33)$$

The median value of S_a corresponding to any level of ductility (d_{roof}/d_y) can be defined combining Equation from 4.30 to 4.32. The relationship between the 16th and 84th fractiles of μ and R can be drawn instead, computing $\beta_{\theta d}$ for a discretised number of R with eq. 4.33, and calculating the 16th and 84th fractiles of μ ($\mu_{16\%}$ and $\mu_{84\%}$), according to the Equations 4.27 and 4.28. $\mu_{16\%}$ - $R_{50\%}$, $\mu_{50\%}$ - $R_{50\%}$ obtained in such way are shown in Figure 4.12.

Figure 4.12 – R - μ relationship.

For any inelastic displacement, and therefore any level of ductility μ the corresponding $R_{50\%}$, $R_{16\%}$, and $R_{84\%}$ values are found interpolating the aforementioned curves. Median R

and its dispersion at ductility levels corresponding to the damage thresholds d_s can thus be determined, and converted into median $S_{a,ds}$ and its dispersion due to record-to-record variability $\beta_{S_{ad}}$, according to equations 4.16 and 4.17.

If dispersion in the damage state threshold is different from zero, different values of ductility limit state are sampled from the lognormal distribution with median the median value of the ductility limit state, and dispersion the input β_{θ_c} . For each of these ductilities the corresponding $R_{50\%}$, $R_{16\%}$, and $R_{84\%}$ values are found interpolating the $\mu_{50\%} - R_{50\%}$, $\mu_{16\%} - R_{50\%}$ and $\mu_{84\%} - R_{50\%}$ curves, and converted into $\hat{S}_{a,ds}$ and $\beta_{S_{ad}}$ according to Equations 4.16 and 4.17. MC random S_a for each of the MC sampled ductility limit states are computed using $\hat{S}_{a,ds}$ and $\beta_{S_{ad}}$, and their median and dispersion are estimated. These parameters constitute the median $\hat{S}_{a,ds}$ and the total dispersion β_{S_a} for the considered damage state. The procedure is repeated for each damage state.

If multiple buildings have been input to derive fragility function for a class of buildings all $\hat{S}_{a,blg}$ and $\beta_{S_{a,blg}}$ are combined in a single lognormal curve as described in section 4.5.1.

In order to use this methodology, it is necessary to load one or multiple capacity curves as described in Section 4.2.1. The capacity curves are then idealised with a bilinear elasto-plastic shape. If the user has already at disposal an idealised multilinear pushover curve for each building, the variable `Idealised` in the csv input file should be set to `TRUE`, and idealised curves should be provided according to what described in section 4.2.1. Then, it is necessary to specify a damage model using the parameter `damage_model` (see Section 4.2.3).

If dispersion due to uncertainty in the limit state definition is different from zero a Monte Carlo sampling needs to be performed to combine it with the record-to-record dispersion. The number of Monte Carlo samples should be defined in the variable `montecarlo_samples`. After importing the module `RGM2007`, it is possible to calculate the parameter of the fragility model, median and dispersion, using the following command:

```
fragility_model = RGM2007.calculate_fragility(capacity_curves, ...
idealised_capacity, damage_model, montecarlo_samples, Sa_ratios)
```

where `Sa_ratios` is the spectral ratio variable, needed to combine together fragility curves for many buildings, as described in Section 4.5.1.

4.6 Record-based nonlinear static procedures

The nonlinear static procedures described in this section allow the calculation of the seismic response of a number of structures (in terms of maximum displacement of the equivalent single degree of freedom (SDOF) system), considering a set of ground motion records (see Section 4.2.2). The development of this methods involved numerical analysis of systems with particular structural and dynamic properties (e.g. periods of vibration, viscous damping, hysteretic behaviour, amongst others) and accelerograms selected for specific regions in the world (e.g. California, South Europe). For these reasons, their applicability to other types of structures and considering a different ground motion records calls for due care. This section provides a brief description of each methodology, but users are advised to fully comprehend the chosen methodology by reading the original publication.

The main results of each of these methodologies is a probability damage matrix (i.e. fraction of assets per damage state for each ground motion record, represented by the variable `PDM`), and the spectral displacement (i.e. expected maximum displacement of the equivalent SDOF system,

represented by the variable Sds) per ground motion record. Using the probability damage matrix (PDM), it is possible to derive a fragility model (i.e. probability of exceedance a number of damage states for a set of intensity measure levels - see Section 4.8.1), or directly a vulnerability model (i.e. distribution of loss ratio for a set of intensity measure levels - see Section ??).

Table 4.7 comprises a probability damage matrix calculated considering 100 assets and 10 ground motion records. For the purposes of this example, an extra column has been added to this table in order to display the peak ground acceleration (PGA) of each accelerogram.

Table 4.7 – *Example of probability damage matrix.*

PGA	No damage	Slight damage	Moderate damage	Extensive damage	Collapse
0.015	1.00	0.00	0.00	0.00	0.00
0.045	0.85	0.12	0.03	0.00	0.00
0.057	0.72	0.20	0.08	0.00	0.00

0.126	0.12	0.34	0.53	0.01	0.00
0.122	0.07	0.18	0.73	0.02	0.00
0.435	0.00	0.00	0.53	0.32	0.15
0.720	0.00	0.00	0.26	0.45	0.29
0.822	0.00	0.00	0.16	0.48	0.36
0.995	0.00	0.00	0.02	0.48	0.50

4.6.1 Vidic and Fajfar 1994

This procedure aims to determine the displacements from an inelastic spectra for systems with a given ductility factor. The inelastic displacement spectra is determined by means of applying a ductility-based reduction factor (C), which depends on the natural period of the system, the given ductility factor, the hysteretic behaviour, the damping model, and the frequency content of the ground motion.

The procedure proposed by (Vidic et al., 1994) was validated by a comparison of the approximate spectra with the “exact” spectra obtained from non-linear dynamic time history analyses. Records from California and Montenegro were used as representative of “standard” ground motion, while the influence of input motion was analysed using other five groups of records (coming from different parts of the world) that represented different types of ground motions. The influence of the hysteretic models was taken into account by considering the bilinear model and the stiffness degrading Q-model. Finally, in order to analyse the effect of damping, two models were considered: “mass-proportional” damping, which assumes a time-independent damping coefficient based on elastic properties, and “instantaneous stiffness-proportional” damping, which assumes a time-dependent damping coefficient based on tangent stiffness. For most cases, a damping ratio of 5% was assumed, although for some systems a value of 2% was adopted.

It is possible to derive approximate strength and displacement inelastic spectra from an elastic pseudo-acceleration spectrum using the proposed modified spectra. In the medium and long-period region, it was observed that the reduction factor is slightly dependant on the period T and is roughly equal to the prescribed ductility (μ). However, in the short-period region, the factor C strongly depends on both T and μ . The influence of hysteretic behaviour and damping can be observed for the whole range of periods. Based on this, a bilinear curve was proposed. Starting in $C = 1$, the value of C increases linearly along the short-period region up to a value

approximately equal to the ductility factor. In the medium- and long-period range, the C-factor remains constant. This is mathematically expressed by the following relationships:

$$C_\mu = \begin{cases} c_1 (\mu - 1)^{c_R} \frac{T}{T_0} + 1, & T \leq T_0 \\ c_1 (\mu - 1)^{c_R} + 1 & T > T_0 \end{cases} \quad (4.34)$$

where:

$$T_0 = c_2 \mu^{c_T} T_c \quad (4.35)$$

And T_c stands for the characteristic spectral period and c_1, c_2, c_R, c_T are constants dependant on the hysteretic behaviour and damping model, as defined in Table 4.8.

Table 4.8 – *Parameters for the estimation of the reduction factor C proposed by (Vidic et al., 1994)*

Hysteresis model	Damping model	c_1	c_2	c_R	c_T
Q	Mass	1.00	0.65	1.00	0.30
Q	Stiffness	0.75	0.65	1.00	0.30
Bilinear	Mass	1.35	0.75	0.95	0.20
Bilinear	Stiffness	1.10	0.75	0.95	0.20

In order to use this methodology, it is necessary to load one or multiple capacity curves as described in Section 4.2.1, as well as a set of ground motion records as explained in Section 4.2.2. Then, it is necessary to specify a damage model using the parameter `damage_model` (see Section 4.2.3), and a damping ratio using the parameter `damping`. It is also necessary to specify the type of hysteresis (Q or bilinear) and damping (mass or stiffness) models as defined in Table 4.8, using the parameters `hysteresis_model` and `damping_model`, respectively. After importing the module `vidic_etal_1994`, it is possible to calculate the distribution of structures across the set of damage state for each ground motion record using the following command:

```
PDM, Sds = vidic_etal_1994.calculate_fragility(capacity_curves,gmrs,...
damage_model,damping)
```

Where PDM (i.e. probability damage matrix) represents a matrix with the number of structures in each damage state per ground motion record, and Sds (i.e. spectral displacements) represents a matrix with the maximum displacement (of the equivalent SDOF) of each structure per ground motion record. the variable PDM can then be used to calculate the mean fragility model as described in Section 4.8.1.

4.6.2 Lin and Miranda 2008

This methodology estimates the maximum inelastic displacement of an existing structure based on the maximum elastic displacement response of its equivalent linear system without the need for iterations, based on the strength ratio R (instead of the most commonly used ductility ratio). In order to evaluate an existing structure, a pushover analysis should be conducted in order to obtain the capacity curve. This curve should be bilinearised in order to obtain the yield strength, f_y , the postyield stiffness ratio, α , and the strength ratio, R . With these parameters, along with the initial period of the system, it is possible to estimate the optimal period shift (i.e. the ratio between the period of the equivalent linear system and the initial period) and the equivalent

viscous damping, ξ_{eq} , of the equivalent linear system, using the following relationships derived by (Lin and Miranda, 2008).

$$\frac{T_{eq}}{T_0} = 1 + \frac{m_1}{T_0^{m_2}} (R^{1.8} - 1) \quad (4.36)$$

$$\xi_{eq} = \xi_0 + \frac{n_1}{T_0^{n_2}} (R - 1) \quad (4.37)$$

Where the coefficients m_1 , m_2 , n_1 , and n_2 depend on the postyield stiffness ratio, as shown in the following Table 4.9.

Table 4.9 – *Parameters for the estimation of the reduction factor C proposed by (Lin and Miranda, 2008)*

α	m_1	m_2	n_1	n_2
0%	0.026	0.87	0.016	0.84
5%	0.026	0.65	0.027	0.55
10%	0.027	0.51	0.031	0.39
20%	0.027	0.36	0.030	0.24

Using ξ_{eq} and the damping modification factor, B (as defined in Table 15.6-1 of NEHRP-2003), it is possible to construct the reduced displacement spectrum, $S_d(T, \xi_{eq})$ from which the maximum displacement demand (i.e. the displacement corresponding to the equivalent system period) can be obtained, using the following equation:

In order to use this methodology, it is necessary to load one or multiple capacity curves as described in Section 4.2.1, as well as a set of ground motion records as explained in Section 4.2.2. Then, it is necessary to specify a damage model using the parameter `damage_model` (see Section 4.2.3). After importing the module `lin_miranda_2008`, it is possible to calculate the distribution of structures across the set of damage state for each ground motion record using the following command:

```
PDM, Sds = lin_miranda_2008.calculate_fragility(capacity_curves,gmrs,...
damage_model,damping)
```

Where PDM (i.e. probability damage matrix) represents a matrix with the number of structures in each damage state per ground motion record, and Sds (i.e. spectral displacements) represents a matrix with the maximum displacement (of the equivalent SDOF) of each structure per ground motion record. the variable PDM can then be used to calculate the mean fragility model as described in Section 4.8.1.

4.6.3 Miranda (2000) for firm soils

This study by Miranda, 2000 aims to quantify the influence of soil conditions, earthquake magnitude, and epicentral distance on the inelastic displacement ratios, C_μ . For two systems with the same mass and period of vibration that have been subjected to the same earthquake ground motion. C_μ can be defined as the ratio of the maximum lateral inelastic displacement

demand of one to the maximum lateral elastic displacement demand on the other, as shown in the following equation:

$$C_\mu = \frac{\Delta_{inelastic}}{\Delta_{elastic}} \quad (4.38)$$

In this study, 264 earthquake acceleration time histories recorded in California (USA) for 12 different events were used. In order to investigate the effect of the soil conditions, the records were classified into three groups: the first one consisted of ground motions recorded on stations located on rock (i.e. average shear-wave velocities >760 m/s). The second group included the records registered on stations on very dense soil or soft rock (i.e. average shear-wave velocities between 360 m/s and 760 m/s). Finally, the third group consisted of ground motion records from stations located on stiff soil (i.e. average shear-wave velocities between 180 m/s and 360 m/s). It was observed that for periods longer than about 1.0 s, the mean inelastic displacement ratios are approximately equal to 1, meaning that, on average, the maximum inelastic displacements are equal to the maximum inelastic displacements. On the other hand, for periods smaller than 1.0 s, the mean inelastic displacement ratios are larger than 1 and strongly depend on the period of vibration and on the level of inelastic deformation. The results of the investigation yielded that for the sites under consideration (i.e. average shear-wave velocities higher than 180 m/s) neither the soil conditions, nor the earthquake magnitude, nor the distance to rupture cause significant differences on the value of C_μ . However, if directivity effects are taken into consideration, the inelastic displacement ratios for periods between 0.1 s and 1.3 s can be larger than those estimated for systems not affected by directivity.

Based on the results of the mean inelastic displacement ratios, nonlinear regression analyses were conducted to estimate the following simplified expression, which allows estimating the inelastic displacement ratio of a system:

$$C_\mu = \left[1 + \left(\frac{1}{\mu} - 1 \right) \exp(-12T\mu^{-0.8}) \right]^{-1} \quad (4.39)$$

Where μ = displacement ductility ratio and T = period of vibration.

In order to use this methodology, it is necessary to load one or multiple capacity curves and a set of ground motion records, as explained in Section 4.2.1 and 4.2.2, respectively. Then, it is necessary to specify a damage model using the parameter `damage_model` (see Section 4.2.3), and a damping ratio using the parameter `damping`. After importing the module `miranda_2000_firm_soils`, it is possible to calculate the distribution of structures across the set of damage states for each ground motion record using the following command:

```
PDM, Sds = miranda_2000_firm_soils.calculate_fragility(capacity_curves,...
gmrs,damage_model,damping)
```

Where PDM (i.e. probability damage matrix) represents a matrix with the number of structures in each damage state per ground motion record, and Sds (i.e. spectral displacements) represents a matrix with the maximum displacement (of the equivalent SDOF) of each structure per ground motion record. the variable PDM can then be used to calculate the mean fragility model as described in Section 4.8.1.

4.6.4 N2 (EC8, CEN 2005)

This simplified nonlinear procedure has been firstly proposed by Fajfar, and it is capable of estimating the seismic response of structures using capacity curves (for the equivalent SDOF)

and response spectra. It is somehow similar to the well-known Capacity Spectrum Method (see Section), but it does not require an iterative process and instead of elastic overdamped spectra, it uses inelastic response spectra. This method is part of recommendations of the Eurocode 8 (CEN, 2005) for the seismic design of new structures, and the capacity curves are usually simplified by a elasto-perfectly plastic relationship.

To estimate the target displacement (δ_t) within this methodology, it is necessary to assess whether the SDOF structure is in the short-period or medium/long-period ranges. To do so, it is necessary to compare the fundamental period of vibration of the structure with the corner period of the ground motion record. If the structure is in the latter category, it is assumed that the target displacement is equal to the elastic spectral displacement for the fundamental period of the idealized SDOF. If on the other hand it is located in the short-period range, a procedure is carried out to evaluate whether the capacity of the SDOF at the yielding point (taken from the bilinear curve) is lower than the spectral acceleration response for the same period. If this is verified, then the structure is assumed to have an elastic response and once again, the target displacement will be equal to the elastic spectral displacement for the fundamental period. In case the capacity is lower than the response for the yielding point, the structure is assumed to have an inelastic response and the following formula is employed to determine the target displacement:

$$\delta_t = \frac{Sd(T_{el})}{q_u} \left(1 + (q_u - 1) \frac{T_c}{T_{el}} \right) Sd(T_{el}) \quad (4.40)$$

Where $Sd(T_{el})$ stands for the spectral displacement for the fundamental period of the idealized SDOF (T_{el}), T_c stands for the corner period and q_u represents the ratio between the spectral acceleration for T_{el} and the acceleration at the yielding point.

It is important to understand that this methodology has been developed originally to be combined with a design or code-based response spectrum, and not with a spectrum derived from real ground motion records. For this reason, its employment in the derivation of fragility functions calls for due care. For instance, the estimation of T_c (which is a fundamental parameter within this methodology) when considering accelerograms is not a trivial task, and various proposals can be found in the literature. For the sake of simplicity, a decision was made to adopt the formula recommended by the ASCE7-10, 2010 which defines:

$$T_c = \frac{Sa(T = 1.0s)}{Sa(T = 0.2s)} \quad (4.41)$$

Despite these caveats, it is worth mentioning that a recent study (Silva et al., 2014b) compared its performance in the derivation of vulnerability functions against nonlinear time history analyses, and concluded that reasonable results can still be obtained.

In order to use this methodology, it is necessary to load one or multiple capacity curves and a set of ground motion records, as explained in Section 4.2.1 and 4.2.2, respectively. Then, it is necessary to specify a damage model using the parameter `damage_model` (see Section 4.2.3), and a damping ratio using the parameter `damping`. After importing the module `N2Method`, it is possible to calculate the distribution of structures across the set of damage states for each ground motion record using the following command:

```
PDM, Sds = N2Method.calculate_fragility(capacity_curves,gmrs,...
damage_model,damping)
```

Where PDM (i.e. probability damage matrix) represents a matrix with the number of structures in each damage state per ground motion record, and Sds (i.e. spectral displacements) represents a matrix with the maximum displacement (of the equivalent SDOF) of each structure per ground motion record. the variable PDM can then be used to calculate the mean fragility model as described in Section 4.8.1.

4.6.5 Capacity Spectrum Method (FEMA, 2005)

The capacity spectrum method (CSM) was initially proposed by (Freeman et al., 1975), and it represents a simplified methodology for many purposes such as the evaluation of a large inventory of buildings, structural assessment of new or existing buildings or to identify the correlation between damage states and levels of ground motion. ATC-40, 1996 proposes three different procedures (A, B and C) for the application of the Capacity Spectrum Method. However, procedure B adopts some simplifications that might not always be valid and procedure C has a very strong graphical component, making it difficult for systematic applications. Hence, procedure A, which is characterized by its intuitiveness and simplicity, has been implemented in the RMTK.

This procedure iteratively compares the capacity and the demand of a structure, using a capacity curve (for the equivalent SDOF) and a damped response spectrum, respectively. The ground motion spectrum is computed for a level of equivalent viscous damping that is estimated as a function of the displacement at which the response spectrum crosses the capacity curve, in order to take into account the inelastic behaviour of the structure. Iterations are needed until there is a match between the equivalent viscous damping of the structure and the damping applied to the spectrum. The final intersection of these two curves approximates the target displacement response of the structure. This result is presented in Figure 4.13 for a "weak" and a "strong" ground motion record.

Figure 4.13 – Assessment of the target displacement for "weak" (left) and "strong" (strong) ground motion record.

The initial proposal of this method was heavily criticized due to its tendency to underestimate the deformation of the structures, which was mostly related with the model employed to calculate the equivalent viscous damping (e.g. Fajfar, 1999; Chopra and Goel, 2000). Thus, in FEMA-440, 2005, some modifications were proposed regarding the calculation of this component. Furthermore, several other models relating an equivalent viscous damping ratio (ξ_{eq}) with a ductility level (μ) have been proposed in the last decades, and implemented in the RMTK. The following list describes these models, and specifies the code that must be defined in the variable `damping_model` in order to follow the associated model in the vulnerability calculations.

- FEMA-440, 2005: This model assumes different expressions to calculate the equivalent viscous damping ratio depending on the ductility level, hysteretic model and post-elastic stiffness. However, for the sake of simplicity, approximate equations have been proposed to calculate ξ_{eq} with any capacity curve, that only depends on the level of ductility, as described below:

For $1.0 < \mu < 4.0$:

$$\xi_{eq} = \xi_0 + 0.049(\mu - 1)^2 - 0.01(\mu - 1)^3 \quad (4.42)$$

For $4.0 \leq \mu \leq 6.5$:

$$\xi_{eq} = \xi_0 + 0.14 + 0.0032(\mu - 1) \quad (4.43)$$

For $\mu > 6.5$:

$$\xi_{eq} = \xi_0 + 0.19 \left[\frac{0.64(\mu - 1) - 1}{[0.64(\mu - 1)]^2} \right] \left(\frac{T_{eff}}{T_0} \right)^2 \quad (4.44)$$

Where ξ_0 stands the initial elastic viscous damping ratio, and T_{eff} represents for the effective period, which for ductility above 6.5 can be calculated using the following expression:

$$T_{eff} = \left\{ 0.89 \left[\sqrt{\frac{(\mu - 1)}{1 + 0.05(\mu - 2)}} \right] + 1 \right\} T_0 \quad (4.45)$$

In order to use this model, the variable `damping_model` must be set to `FEMA_2005`.

- Kowalsky, 1994: This model establishes a relationship between the equivalent viscous damping ratio and a ductility level and a post-yield stiffness ratio α , as defined by the following equation:

$$\xi_{eq} = \xi_0 + \frac{1}{\pi} \left[1 - \frac{(1 - \alpha)}{\sqrt{\mu}} - \alpha\sqrt{\mu} \right] \quad (4.46)$$

In order to use this model, the variable `damping_model` must be set to `Kowalsky_1994`.

- (Iwan, 1980): This model was developed using a limited number of ground motion records and a single hysteretic model, leading to the following equation:

$$\xi_{eq} = \xi_0 + 0.0587(\mu - 1)^0.371 \quad (4.47)$$

In order to use this model, the variable `damping_model` must be set to `Iwan_1980`.

- Gulkan and Sozen, 1974: This model was derived considering the Takeda hysteretic for elastoplastic systems calibrated with experimental shaking-table results of a number of reinforced concrete frames. The equivalent viscous damping ratio is calculated using the following ductility-dependent formula:

$$\xi_{eq} = \xi_0 + 0.2 \left(1 - \frac{1}{\sqrt{\mu}} \right) \quad (4.48)$$

In order to use this model, the variable `damping_model` must be set to `Gulkan_Sozen_1974`.

- Priestley et al., 2007: These Authors proposed different models depending on the structure type. Currently, three models proposed by this study have been implemented, as described below:

For reinforced concrete frame structures:

$$\xi_{eq} = 0.05 + 0.565 \left(\frac{\mu - 1}{\pi\mu} \right) \quad (4.49)$$

To use this model set the variable `damping_model` to `Priesley_et_al2007_frames`.

For reinforced concrete walls structures:

$$\xi_{eq} = 0.05 + 0.444 \left(\frac{\mu - 1}{\pi\mu} \right) \quad (4.50)$$

To use this model set the variable `damping_model` to `Priesley_et_al2007_walls`.

For steel structures:

$$\xi_{eq} = 0.05 + 0.577 \left(\frac{\mu - 1}{\pi\mu} \right) \quad (4.51)$$

To use this model set the variable `damping_model` to `Priesley_et_al2007_steel`.

- Calvi, 1999: This Author proposed a relationship between the equivalent viscous damping ratio and ductility following the expression below:

$$\xi_{eq} = \xi_0 + a \left(1 - \frac{1}{\mu^b} \right) \quad (4.52)$$

Where a and b are constants that vary between 20 and 30, and 0.5 and 1, respectively, depending on the hysteretic properties of the structure. Thus, this model can be employed for various structure types, by adjusting these two constants. Given the fact that most of the current damping models have been derived or calibrated for reinforced concrete structures, a decision was made to adjust these parameters for the assessment of masonry structures. The a and b constants have been set to 25 and 0.5, respectively, as proposed by Borzi et al., 2008a. Nonetheless, due to the open and transparent architecture of the RMTK, any user can modify these parameters.

In order to use this model, the variable `damping_model` must be set to `Calvi_1999`.

The performance point (or target displacement) calculated within this methodology is equivalent to what would be obtained by subjecting the equivalent single degree of freedom oscillator to a nonlinear time history analysis. Then, estimated target displacement can be used to allocate the structure in a damage state, based on a pre-established set of displacement thresholds. This process can be repeated several times considering other ground motion records, as well as structures (i.e. building class).

In order to use this methodology, it is necessary to load one or multiple capacity curves and a set of ground motion records, as explained in Section 4.2.1 and 4.2.2, respectively. Then, it is necessary to specify a damage model using the parameter `damage_model` (see Section 4.2.3), and a damping ratio using the parameter `damping`. After importing the module `capacitySpectrumMethod`, it is possible to calculate the distribution of structures across the set of damage states for each ground motion record using the following command:

```
PDM, Sds = capacitySpectrumMethod.calculate_fragility(capacity_curves,...
gmrs,damage_model,damping)
```

Where PDM (i.e. probability damage matrix) represents a matrix with the number of structures in each damage state per ground motion record, and Sds (i.e. spectral displacements) represents a matrix with the maximum displacement (of the equivalent SDOF) of each structure per ground motion record. the variable PDM can then be used to calculate the mean fragility model as described in Section 4.8.1.

4.6.6 DBELA (Silva et al. 2013)

The Displacement-based Earthquake Loss Assessment (DBELA) methodology builds upon the urban assessment methodology proposed by Calvi, 1999, in which the principles of structural mechanics and seismic response of buildings are used to estimate the seismic vulnerability of classes of buildings. The current implementation of the RMTK is only compatible with bare or infilled frame reinforced concrete structures.

In this method, the displacement capacity and demand for a number of limit states needs to be calculated. Each limit state marks the threshold between the levels of damage that a building might withstand, usually described by a reduction in strength or by exceedance of certain displacement/drift levels. Once these parameters are obtained, the displacement capacity of the first limit state is compared with the respective demand. If the demand exceeds the capacity, the next limit states need to be checked successively, until the demand no longer exceeds the capacity and the building damage state can be defined. If the demand also exceeds the capacity of the last limit state, the building is assumed to have collapsed. This procedure is schematically depicted in Figure 4.14, in which the capacities for three limit states are represented by Δ_i and the associated demand by Sd_i . In this example, the demand exceeds the capacity in the first and second limit state but not in the third limit state, thus allocating the building to the third damage state.

The calculation of the displacement capacity at each limit state is explained in the Model Generation Section (4.3), as this methodology can be employed to generate large sets of capacity curves (S_a versus S_d), which can be combined with other methodologies besides DBELA to derive fragility functions. Instead, this section is focused on describing how the seismic demand is handled in this methodology.

The demand is represented by a displacement spectrum which can be described as the expected displacement induced by an earthquake on a single-degree-of-freedom (SDOF) oscillator with a given period of vibration and viscous damping. This demand is initially calculated for a 5% viscous damping, and later modified for each limit state using a correction factor (η), representative of the equivalent viscous damping and ductility at the associated damage state. In the Eurocode 8 (CEN, 2005), the following equation is proposed for the calculation of the

Figure 4.14 – Comparison between limit state capacity and the associated demand (adapted from Bal et al., 2010).

correction factor:

$$\eta_{LS_i} = \sqrt{\frac{10}{5 + \xi_{eq_i}}} \quad (4.53)$$

Where ξ_{eq_i} stands for the equivalent viscous damping at the limit state i . Although in theory there is a multitude of damping models in the literature that could be used to calculate this equivalent viscous damping (see Section 4.6.5 for a description of the damping models implemented within the Capacity Spectrum Method), this method has been tested following the proposals by Priestley et al., 2007 for reinforced concrete frames (e.g. Bal et al., 2010 Silva et al., 2013). This model uses the following equation:

$$\xi_{eq} = 0.05 + 0.565 \left(\frac{\mu - 1}{\pi \mu} \right) \quad (4.54)$$

Where μ_i stands for the ductility at the limit state i (assumed as the ratio between Δ_i and Δ_y). More accurate approaches have recently been proposed to estimate the correction factors (η), considering additional parameters, such as the magnitude or source-to-site distance (Rezaeian et al., 2012).

With regards to the calculation of the yielding period (T_y) for bare frame structures, Crowley and Pinho, 2004 and Crowley et al., 2008 proposed a relationship between the period and the total height (H_T) of $0.10H_T$ and $0.07H_T$ for structures without and with lateral load design, respectively. For infilled frames, a relation equal to $0.06H_T$ has been recommended by Crowley and Pinho, 2006 for structures without lateral load design. The elongated period of vibration for any of the limit states (T_{LS_i}) can be computed using the following formula:

$$T_{LS_i} = T_y \sqrt{\frac{\mu_i}{1 + \alpha \mu_i - \alpha}} \quad (4.55)$$

where α stands for the post-yield stiffness ratio. In cases where this ratio can be assumed as zero, the relation between T_{LS_i} and T_y will depend purely on the limit state ductility as follows:

$$T_{LS_i} = T_y \sqrt{\mu_i} \quad (4.56)$$

In order to use this methodology, it is necessary to first assess the capacity displacement of one or multiple assets, following the DBELA approach explained in Section 4.3.1 (Model Generator). Moreover, a set of ground motion records and a damage model should be provided, as explained in Section 4.2.2 and 4.2.3), respectively. The type of structures that are being evaluated should be specified using the parameter `structure_type`. Currently this module of the RMTK accepts the options `bare frame` and `infilled frame`. After importing the module DBELA, it is possible to calculate the distribution of structures across the set of damage states for each ground motion record using the following command:

```
PDM, Sds = DBELA.calculate_fragility(capacity_curves,gmrs,...
damage_model,structure_type)
```

Where PDM (i.e. probability damage matrix) represents a matrix with the number of structures in each damage state per ground motion record, and Sds (i.e. spectral displacements) represents a matrix with the maximum displacement (of the equivalent SDOF) of each structure per ground motion record. the variable PDM can then be used to calculate the mean fragility model as described in Section 4.8.1.

4.7 Nonlinear time-history analysis in Single Degree of Freedom (SDOF) Oscillators

This methodology performs a series of non-linear time history analyses (NLTHA) over one or multiple single degree of freedom (SDOF) systems. In order to determine the structural capacity of the system(s) under analysis, it is necessary to identify the relationship between the base shear and roof displacement (i.e. pushover curve). This curve can be further modified in order to obtain the curve corresponding to an equivalent SDOF, or capacity curve. It is typically assumed that the fundamental mode of vibration corresponds with the predominant response of the structure. Under this hypothesis, the capacity curve usually represents the first mode of response of the structure. This is usually valid for buildings with fundamental periods of vibration up to approximately 1.0 s. Otherwise, higher modes should be taken into account. Along with the capacity curve, it is necessary to specify either the mass or the fundamental period of vibration of the SDOF system.

On the other hand, the demand is represented by a set of ground motion records. The response of each structure is given by the solution of the equation of motion for an inelastic SDOF under earthquake excitation:

$$m\ddot{u}(t) + c\dot{u}(t) + ku(t) = p(t) \quad (4.57)$$

Where u , \dot{u} and \ddot{u} stand for the displacement, velocity and acceleration, respectively, over time (t), and p represents an external excitation. In this method, the behaviour of the SDOF is modelled by a capacity curve that must follow the structure illustrated in Figure 4.15.

Six relevant points should be defined in this curve. The first one corresponds to the origin, (0, 0). The next point, (S_{dy} , S_{ay}), corresponds to the yielding point of the structure, i.e. the point beyond which the structure no longer displays an elastic behaviour. The following two points are defined as any two intermediate points between the yield point and the ultimate point which can be used to represent particular structural properties, such as reduction of stiffness due to collapse of infill pannels or softening behavior due to P-delta effects. The ultimate point (S_{du} , S_{au}) corresponds to the point of maximum displacement of the structure. Finally, the last point (S_{du} , 0) is just a control point to define the hysteretic model, in case degradation is considered

Figure 4.15 – Representation of the capacity curve required to represent the structural capacity of the SDOF system.

in the analysis. For the purposes of the RMTK, the first five points must be provided as input. The nonlinear time history analysis are performed using the open-source software for structural analysis OpenSees (McKenna et al., 2000). It is important to understand the GEM Foundation does not have authorization to distribute this tool, and therefore in order to use this methodology, users are expected to download OpenSEES (<http://opensees.berkeley.edu/>), and allocate it in the appropriate folder (vulnerability/derivation_fragility/NLTHA_on_SDOF).

In order to use this methodology, it is necessary to load one or multiple capacity curves and a set of ground motion records, as explained in Section 4.2.1 and 4.2.2, respectively. Then, it is necessary to specify a damage model using the parameter `damage_model` (see Section 4.2.3). The damping ratio must be defined using the parameter `damping`, and if structural degradation should be considered in the analysis, it is necessary to set the parameter `degradation` to `True`. After importing the module `NLTHA_on_SDOF`, it is possible to calculate the distribution of structures across the set of damage states for each ground motion record using the following command:

```
PDM, Sds = NLTHA_on_SDOF.calculate_fragility(capacity_curves,gmrs,...
damage_model,damping)
```

Where PDM (i.e. probability damage matrix) represents a matrix with the number of structures in each damage state per ground motion record, and Sds (i.e. spectral displacements) represents a matrix with the maximum displacement (of the equivalent SDOF) of each structure per ground motion record. the variable PDM can then be used to calculate the mean fragility model as described in Section 4.8.1.

4.8 Derivation of fragility and vulnerability functions

4.8.1 Derivation of fragility functions

4.8.2 Derivation of vulnerability functions

To be completed by Anirudh.

Part I

Appendices

A. The 10 Minute Guide to Python

The RMTK is intended to be used by scientists and engineers without the necessity of having an existing knowledge of Python. It is hoped that the examples contained in this manual should provide enough context to allow the user to understand how to use the tools for their own needs. In spite of this, however, an understanding of the fundamentals of the Python programming language can greatly enhance the user experience and permit the user to join together the tools in a workflow that best matches their needs.

The aim of this appendix is therefore to introduce some fundamentals of the Python programming language in order to help understand how, and why, the HMTK can be used in a specific manner. If the reader wishes to develop their knowledge of the Python programming language beyond the examples shown here, there is a considerable body of literature on the topic from both a scientific and developer perspective.

A.1 Basic Data Types

Fundamental to the use of the HMTK is an understanding of the basic data types Python recognises:

A.1.1 Scalar Parameters

- **float** A floating point (decimal) number. If the user wishes to enter in a floating point value then a decimal point must be included, even if the number is rounded to an integer.

```
1 | >> a = 3.5
2 | >> print a, type(a)
3 | 3.5 <type 'float'>
```

- **integer** An integer number. If the decimal point is omitted for a floating point number the number will be considered an integer

```
1 | >> b = 3
2 | >> print b, type(b)
3 | 3 <type 'int'>
```

The functions `float()` and `int()` can convert an integer to a float and vice-versa. Note that taking `int()` of a fraction will round the fraction down to the nearest integer

```

1 | >> float(b)
2 | 3
3 | >> int(a)
4 | 3

```

- **string** A text string (technically a “list” of text characters). The string is indicated by the quotation marks ”something” or ’something else’

```

1 | >> c = "apples"
2 | >> print c, type(c)
3 | apples <type 'str'>

```

- **bool** For logical operations python can recognise a variable with a boolean data type (True / False).

```

1 | >> d = True
2 | >> if d:
3 |     print "y"
4 | else:
5 |     print "n"
6 | y
7 | >> d = False
8 | >> if d:
9 |     print "y"
10 | else:
11 |     print "n"
12 | n

```

Care should be taken in Python as the value 0 and 0.0 are both recognised as False if applied to a logical operation. Similarly, booleans can be used in arithmetic where True and False take the values 1 and 0 respectively

```

1 | >> d = 1.0
2 | >> if d:
3 |     print "y"
4 | else:
5 |     print "n"
6 | y
7 | >> d = 0.0
8 | >> if d:
9 |     print "y"
10 | else:
11 |     print "n"
12 | n

```

Scalar Arithmetic

Scalars support basic mathematical operations (# indicates a comment):

```

1 | >> a = 3.0
2 | >> b = 4.0
3 | >> a + b # Addition
4 | 7.0
5 | >> a * b # Multiplication
6 | 12.0
7 | >> a - b # Subtraction
8 | -1.0
9 | >> a / b # Division
10 | 0.75
11 | >> a ** b # Exponentiation
12 | 81.0
13 | # But integer behaviour can be different!
14 | >> a = 3; b = 4

```

```

15 |>> a / b
16 | 0
17 |>> b / a
18 | 1

```

A.1.2 Iterables

Python can also define variables as lists, tuples and sets. These data types can form the basis for iterable operations. It should be noted that unlike other languages, such as Matlab or Fortran, Python iterable locations are zero-ordered (i.e. the first location in a list has an index value of 0, rather than 1).

- **List** A simple list of objects, which have the same or different data types. Data in lists can be re-assigned or replaced

```

1 |>> a_list = [3.0, 4.0, 5.0]
2 |>> print a_list
3 | [3.0, 4.0, 5.0]
4 |>> another_list = [3.0, "apples", False]
5 |>> print another_list
6 | [3.0, 'apples', False]
7 |>> a_list[2] = -1.0
8 | a_list = [3.0, 4.0, -1.0]

```

- **Tuples** Collections of objects that can be iterated upon. As with lists, they can support mixed data types. However, objects in a tuple cannot be re-assigned or replaced.

```

1 |>> a_tuple = (3.0, "apples", False)
2 |>> print a_tuple
3 | (3.0, 'apples', False)
4 | # Try re-assigning a value in a tuple
5 |>> a_tuple[2] = -1.0
6 | TypeError                                Traceback (most recent call last)
7 | <ipython-input-43-644687cfd23c> in <module>()
8 | ----> 1 a_tuple[2] = -1.0
9 |
10 | TypeError: 'tuple' object does not support item assignment

```

- **Range** A range is a convenient function to generate arithmetic progressions. They are called with a start, a stop and (optionally) a step (which defaults to 1 if not specified)

```

1 |>> a = range(0, 5)
2 |>> print a
3 | [0, 1, 2, 3, 4] # Note that the stop number is not
4 |                 # included in the set!
5 |>> b = range(0, 6, 2)
6 |>> print b
7 | [0, 2, 4]

```

- **Sets** A set is a special case of an iterable in which the elements are unordered, but contains more enhanced mathematical set operations (such as intersection, union, difference, etc.)

```

1 |>> from sets import Set
2 |>> x = Set([3.0, 4.0, 5.0, 8.0])
3 |>> y = Set([4.0, 7.0])
4 |>> x.union(y)
5 | Set([3.0, 4.0, 5.0, 7.0, 8.0])
6 |>> x.intersection(y)
7 | Set([4.0])
8 |>> x.difference(y)
9 | Set([8.0, 3.0, 5.0]) # Notice the results are not ordered!

```

Indexing

For some iterables (including lists, sets and strings) Python allows for subsets of the iterable to be selected and returned as a new iterable. The selection of elements within the set is done according to the index of the set.

```

1 >> x = range(0, 10) # Create an iterable
2 >> print x
3 [0, 1, 2, 3, 4, 5, 6, 7, 8, 9]
4 >> print x[0] # Select the first element in the set
5 0 # recall that iterables are zero-ordered!
6 >> print x[-1] # Select the last element in the set
7 9
8 >> y = x[:] # Select all the elements in the set
9 >> print y
10 [0, 1, 2, 3, 4, 5, 6, 7, 8, 9]
11 >> y = x[:4] # Select the first four element of the set
12 >> print y
13 [0, 1, 2, 3]
14 >> y = x[-3:] # Select the last three elements of the set
15 >> print y
16 [7, 8, 9]
17 >> y = x[4:7] # Select the 4th, 5th and 6th elements
18 >> print y
19 [4, 5, 6]

```

A.1.3 Dictionaries

Python is capable of storing multiple data types associated with a map of variable names inside a single object. This is called a “Dictionary”, and works in a similar manner to a “data structure” in languages such as Matlab. Dictionaries are used frequently in the HMTK as ways of structuring inputs to functions that share a common behaviour but may take different numbers and types of parameters on input.

```

1 >> earthquake = {"Name": "Parkfield",
2                  "Year": 2004,
3                  "Magnitude": 6.1,
4                  "Recording Agencies" = ["USGS", "ISC"]}
5 # To call or view a particular element in a dictionary
6 >> print earthquake["Name"], earthquake["Magnitude"]
7 Parkfield 6.1

```

A.1.4 Loops and Logicals

Python’s syntax for undertaking logical operations and iterable operations is relatively straightforward.

Logical

A simple logical branching structure can be defined as follows:

```

1 >> a = 3.5
2 >> if a <= 1.0:
3     b = a + 2.0
4     elif a > 2.0:
5         b = a - 1.0
6     else:
7         b = a ** 2.0
8 >> print b
9 2.5

```

Boolean operations can are simply rendered as and, or and not.

```
1 >> a = 3.5
2 >> if (a <= 1.0) or (a > 3.0):
3     b = a - 1.0
4     else:
5         b = a ** 2.0
6 >> print b
7 2.5
```

Looping

There are several ways to apply looping in python. For simple mathematical operations, the simplest way is to make use of the **range** function:

```
1 >> for i in range(0, 5):
2     print i, i ** 2
3 0 0
4 1 1
5 2 4
6 3 9
7 4 16
```

The same could be achieved using the while function (though possibly this approach is far less desirable depending on the circumstance):

```
1 >> i = 0
2 >> while i < 5:
3     print i, i ** 2
4     i += 1
5 0 0
6 1 1
7 2 4
8 3 9
9 4 16
```

A for loop can be applied to any iterable:

```
1 >> fruit_data = ["apples", "oranges", "bananas", "lemons",
2                 "cherries"]
3 >> i = 0
4 >> for fruit in fruit_data:
5     print i, fruit
6     i += 1
7 0 apples
8 1 oranges
9 2 bananas
10 3 lemons
11 4 cherries
```

The same results can be generated, arguably more cleanly, by making use of the **enumerate** function:

```
1 >> fruit_data = ["apples", "oranges", "bananas", "lemons",
2                 "cherries"]
3 >> for i, fruit in enumerate(fruit_data):
4     print i, fruit
5 0 apples
6 1 oranges
7 2 bananas
8 3 lemons
9 4 cherries
```

As with many other programming languages, Python contains the statements **break** to break out of a loop, and **continue** to pass to the next iteration.

```
1 >> i = 0
2 >> while i < 10:
3     if i == 3:
4         i += 1
5         continue
6     elif i == 5:
7         break
8     else:
9         print i, i ** 2
10    i += 1
11 0 0
12 1 1
13 2 4
14 4 16
```

A.2 Functions

Python easily supports the definition of functions. A simple example is shown below. *Pay careful attention to indentation and syntax!*

```
1 >> def a_simple_multiplier(a, b):
2     """
3     Documentation string - tells the reader the function
4     will multiply two numbers, and return the result and
5     the square of the result
6     """
7     c = a * b
8     return c, c ** 2.0
9
10 >> x = a_simple_multiplier(3.0, 4.0)
11 >> print x
12 (12.0, 144.0)
```

In the above example the function returns two outputs. If only one output is assigned then that output will take the form of a tuple, where the elements correspond to each of the two outputs. To assign directly, simply do the following:

```
1 >> x, y = a_simple_multiplier(3.0, 4.0)
2 >> print x
3 12.0
4 >> print y
5 144.0
```

A.3 Classes and Inheritance

Python is one of many languages that is fully object-oriented, and the use (and terminology) of objects is prevalent throughout the HMTK and this manual. A full treatise on the topic of object oriented programming in Python is beyond the scope of this manual and the reader is referred to one of the many textbooks on Python for more examples

A.3.1 Simple Classes

A class is an object that can hold both attributes and methods. For example, imagine we wish to convert an earthquake magnitude from one scale to another; however, if the earthquake occurred after a user-defined year we wish to use a different formula. This could be done by a method, but we can also use a class:

```

1  >> class MagnitudeConverter(object):
2      """
3          Class to convert magnitudes from one scale to another
4      """
5      def __init__(self, converter_year):
6          """
7          """
8          self.converter_year = converter_year
9
10     def convert(self, magnitude, year):
11         """
12         Converts the magnitude from one scale to another
13         """
14         if year < self.converter_year:
15             converted_magnitude = -0.3 + 1.2 * magnitude
16         else:
17             converted_magnitude = 0.1 + 0.94 * magnitude
18         return converted_magnitude
19
20 >> converter1 = MagnitudeConverter(1990)
21 >> mag_1 = converter1.convert(5.0, 1987)
22 >> print mag_1
23 5.7
24 >> mag_2 = converter1.convert(5.0, 1994)
25 >> print mag_2
26 4.8
27 # Now change the conversion year
28 >> converter2 = MagnitudeConverter(1995)
29 >> mag_1 = converter2.convert(5.0, 1987)
30 >> print mag_1
31 5.7
32 >> mag_2 = converter2.convert(5.0, 1994)
33 >> print mag_2
34 5.7

```

In this example the class holds both the attribute `converter_year` and the method to convert the magnitude. The class is created (or “instantiated”) with only the information regarding the cut-off year to use the different conversion formulae. Then the class has a method to convert a specific magnitude depending on its year.

A.3.2 Inheritance

Classes can be useful in many ways in programming. One such way is due to the property of inheritance. This allows for classes to be created that can inherit the attributes and methods of another class, but permit the user to add on new attributes and/or modify methods.

In the following example we create a new magnitude converter, which may work in the same way as the `MagnitudeConverter` class, but with different conversion methods.

```

1  >> class NewMagnitudeConverter(MagnitudeConverter):
2      """
3          A magnitude converter using different conversion
4          formulae
5      """
6      def convert(self, magnitude, year):
7          """
8          Converts the magnitude from one scale to another
9          - differently!!!
10         """
11         if year < self.converter_year:
12             converted_magnitude = -0.1 + 1.05 * magnitude

```

```

13         else:
14             converted_magnitude = 0.4 + 0.8 * magnitude
15             return converted_magnitude
16 # Now compare converters
17 >> converter1 = MagnitudeConverter(1990)
18 >> converter2 = NewMagnitudeConverter(1990)
19 >> mag1 = converter1.convert(5.0, 1987)
20 >> print mag1
21 5.7
22 >> mag2 = converter2.convert(5.0, 1987)
23 >> print mag2
24 5.15
25 >> mag3 = converter1.convert(5.0, 1994)
26 >> print mag3
27 4.8
28 >> mag4 = converter2.convert(5.0, 1994)
29 >> print mag4
30 4.4

```

A.3.3 Abstraction

Inspection of the HMTK code (<https://github.com/GEMScienceTools/hmtk>) shows frequent usage of classes and inheritance. This is useful in our case if we wish to make available different methods for the same problem. In many cases the methods may have similar logic, or may provide the same types of outputs, but the specifics of the implementation may differ. Functions or attributes that are common to all methods can be placed in a “Base Class”, permitting each implementation of a new method to inherit the “Base Class” and its functions/attributes/behaviour. The new method will simply modify those aspects of the base class that are required for the specific method in question. This allows functions to be used interchangeably, thus allowing for a “mapping” of data to specific methods.

An example of abstraction is shown using our two magnitude converters shown previously. Imagine that a seismic recording network (named “XXX”) has a model for converting from their locally recorded magnitude to a reference global scale (for the purposes of narrative, imagine that a change in recording procedures in 1990 results in a change of conversion model). A different recording network (named “YYY”) has a different model for converting their local magnitude to a reference global scale (and we imagine they also changed their recording procedures, but they did so in 1994). We can create a mapping that would apply the correct conversion for each locally recorded magnitude in a short catalogue, provided we know the local magnitude, the year and the recording network.

```

1 >> CONVERSION_MAP = {"XXX": MagnitudeConverter(1990),
2                       "YYY": NewMagnitudeConverter(1994)}
3 >> earthquake_catalogue = [(5.0, "XXX", 1985),
4                             (5.6, "YYY", 1992),
5                             (4.8, "XXX", 1993),
6                             (4.4, "YYY", 1997)]
7 >> for earthquake in earthquake_catalogue:
8     converted_magnitude = \ # Line break for long lines!
9         CONVERSION_MAP[earthquake[1]].convert(earthquake[0],
10                                                earthquake[2])
11     print earthquake, converted_magnitude
12 (5.0, "XXX", 1985) 5.7
13 (5.6, "YYY", 1992) 5.78
14 (4.8, "XXX", 1993) 4.612
15 (4.4, "YYY", 1997) 3.92

```

So we have a simple magnitude homogenisor that applies the correct function depending on

the network and year. It then becomes a very simple matter to add on new converters for new agencies; hence we have a “toolkit” of conversion functions!

A.4 Numpy/Scipy

Python has two powerful libraries for undertaking mathematical and scientific calculation, which are essential for the vast majority of scientific applications of Python: Numpy (for multi-dimensional array calculations) and Scipy (an extensive library of applications for maths, science and engineering). Both libraries are critical to both OpenQuake and the HMTK. Each package is so extensive that a comprehensive description requires a book in itself. Fortunately there is abundant documentation via the online help for Numpy www.numpy.org and Scipy www.scipy.org, so we do not need to go into detail here.

The particular facet we focus upon is the way in which Numpy operates with respect to vector arithmetic. Users familiar with Matlab will recognise many similarities in the way the Numpy package undertakes array-based calculations. Likewise, as with Matlab, code that is well vectorised is significantly faster and more efficient than the pure Python equivalent.

The following shows how to undertake basic array arithmetic operations using the Numpy library

```

1 >> import numpy as np
2 # Create two vectors of data, of equal length
3 >> x = np.array([3.0, 6.0, 12.0, 20.0])
4 >> y = np.array([1.0, 2.0, 3.0, 4.0])
5 # Basic arithmetic
6 >> x + y # Addition (element-wise)
7 np.array([4.0, 8.0, 15.0, 24.0])
8 >> x + 2 # Addition of scalar
9 np.array([5.0, 8.0, 14.0, 22.0])
10 >> x * y # Multiplication (element-wise)
11 np.array([3.0, 12.0, 36.0, 80.0])
12 >> x * 3.0 # Multiplication by scalar
13 np.array([9.0, 18.0, 36.0, 60.0])
14 >> x - y # Subtraction (element-wise)
15 np.array([2.0, 4.0, 9.0, 16.0])
16 >> x - 1.0 # Subtraction of scalar
17 np.array([2.0, 5.0, 11.0, 19.0])
18 >> x / y # Division (element-wise)
19 np.array([3.0, 3.0, 4.0, 5.0])
20 >> x / 2.0 # Division over scalar
21 np.array([1.5, 3.0, 6.0, 10.0])
22 >> x ** y # Exponentiation (element-wise)
23 np.array([3.0, 36.0, 1728.0, 160000.0])
24 >> x ** 2.0 # Exponentiation (by scalar)
25 np.array([9.0, 36.0, 144.0, 400.0])

```

Numpy contains a vast set of mathematical functions that can be operated on a vector (e.g.):

```

1 >> x = np.array([3.0, 6.0, 12.0, 20.0])
2 >> np.exp(x)
3 np.array([2.00855369e+01, 4.03428793e+02, 1.62754791e+05,
4         4.85165195e+08])
5 # Trigonometry
6 >> theta = np.array([0., np.pi / 2.0, np.pi, 1.5 * np.pi])
7 >> np.sin(theta)
8 np.array([0.0000, 1.0000, 0.0000, -1.0000])
9 >> np.cos(theta)
10 np.array([1.0000, 0.0000, -1.0000, 0.0000])

```

Some of the most powerful functions of Numpy, however, come from its logical indexing:

```
1 >> x = np.array([3.0, 5.0, 12.0, 21.0, 43.0])
2 >> idx = x >= 10.0    # Perform a logical operation
3 >> print idx
4 np.array([False, False, True, True, True])
5 >> x[idx]             # Return an array consisting of elements
6                       # for which the logical operation returned True
7 np.array([12.0, 21.0, 43.0])
```

Create, index and slice n-dimensional arrays:

```
1 >> x = np.array([[3.0, 5.0, 12.0, 21.0, 43.0],
2                  [2.0, 1.0, 4.0, 12.0, 30.0],
3                  [1.0, -4.0, -2.1, 0.0, 92.0]])
4 >> np.shape(x)
5 (3, 5)
6 >> x[:, 0]
7 np.array([3.0, 2.0, 1.0])
8 >> x[1, :]
9 np.array([2.0, 1.0, 4.0, 12.0, 30.0])
10 >> x[:, [1, 4]]
11 np.array([[ 5.0, 43.0],
12           [ 1.0, 30.0],
13           [-4.0, 92.0]])
```

The reader is referred to the online documentation for the full set of functions!
